Hester TR, Codner MA, McCord CD, et al. Evolution of technique of the direct transblepharoplasty approach for the correction of lower lid and midfacial aging: maximizing results and minimizing complications in a 5-year experience. *Plast Reconstr Surg* 105:393-406; discussion 407-408, 2000.

The purpose of this article is twofold: to provide a comprehensive retrospective evaluation of the value and promise of the technique, and to present a comprehensive discussion of the pitfalls and complications that have been associated with use of this technique. In addition, technical modifications that may lower the rate of morbidity associated with the use of the procedure are described. The authors' experience with transblepharoplasty midface and lower lid rejuvenation confirms that the key to preventing complications lies in the surgeon's ability to manage the lower lid skin/muscle excess that is returned to the orbit after vertical elevation of the midface.

McCord CD, Codner MA, Hester TR. Redraping the inferior orbicularis arc. *Plast Reconstr Surg* 102:2471-2479, 1998.

The authors discuss the surgical technique of redraping of the inferior arc of the orbicularis oculi muscle, used primarily to produce lower lid and midfacial smoothing in patients undergoing aesthetic surgery. They also describe the technique modifications necessary for treating patients with prominent eyes and distensible lower lids as well as adjunctive procedures.

Psillakis JM, Rumley TO, Carmagos A. Subperiosteal approach as an improved concept for correction of the aging face. *Plast Reconstr Surg* 82:383-394, 1988.

A harmonious facial appearance is determined by a balanced relationship among all tissues of the face. With advancing age, balance is lost among the bone, muscle, fat, and skin as progressive changes occur in their volume, shape, position, and consistency. The authors present the subperiosteal rhytidectomy technique to achieve natural results of the upper and central face, eyebrows, periorbital, external canthus, cheeks, and nasolabial folds. They also include patient results and discuss complications.

Sullivan SA, Dailey RA. Endoscopic subperiosteal midface lift: surgical technique with indications and outcomes. *Ophthal Plast Reconstr Surg* 18:319-330; discussion 329-330, 2002.

The authors review the indications for and the surgical technique of the endoscopic subperiosteal midface lift. They also present clinical outcomes in 22 consecutive patients. They found this technique to be an effective method for elevating the midface and achieving a more youthful appearance.

CHAPTER 38

Endoscopic Rejuvenation of the Midface

RENATO SALTZ, CARLOS CASAGRANDE,
ANDERSON SACILOTO,
GABRIELE CÁCERES MIOTTO

A better understanding of the pathophysiology of midface aging and the intrinsic anatomic structures involved in this process has allowed plastic surgeons to develop safe techniques for midface rejuvenation, and significant progress has been made in recent years. Many different approaches have been introduced for the treatment of the aging midface, including these areas:

- Lower eyelid
- Face lift
- Open temporal incision
- Use of barbed sutures
- Endoscopic temporal and oral incisions

The endoscopic temporal approach for the treatment of the midface has obvious advantages. It provides a safe plane of dissection along the deep temporal fascia and along the subperiosteal plane of the midface or the forehead. It can easily be combined with an endoscopic brow lift when necessary. It provides excellent visualization of the midface anatomy and permits easy fixation, regardless of the method chosen. Because of the extensive dissection and creation of an excellent optical cavity in the midface pocket, one can often eliminate the need for an intraoral incision, thus decreasing the possible risk of infection. Furthermore, endoscopic midface suspension has, in our hands, been shown to be a safe, reproducible technique with good long-term results. Patients appear to be more satisfied because the scars are smaller, there is less bruising, and recovery is faster. Endoscopic magnification provides better visualization of the complex midface anatomy, resulting in reduced morbidity.

Pertinent Anatomy

Success with any operation for facial rejuvenation requires a basic understanding of the aesthetic subunits and anatomic structures of the face and how they are affected by the aging process; these should be studied and respected to obtain a harmonious result. It is important to know which structures need to be altered and then to match the correct treatment with the most appropriate technique.

Midface aging is characterized by four anatomic changes:

1. Descent of the malar fat pad
2. Descent of the lid-cheek junction
3. Increase in prominence of the nasolabial folds
4. Loss of cheek projection

The changes associated with midface aging occur as a result of ptosis of the malar fat pads, with an inferior medial sliding of this tissue. Concomitantly, cutaneous and ligamentous laxity results in the descent of the facial muscles: the zygomaticus minor and major and the levator of the upper lip. Together these changes accentuate the nasolabial groove and contribute to flattening of the malar area.

An excess of tissue known as the *malar bag* or *festoon* may also develop. This is a thick fat layer located between the skin and the superficial musculoaponeurotic system (SMAS). Other changes include maxillary reabsorption and ptosis of the corners of the mouth, resulting in what patients refer to as a “sadistic smile.” This aging process also creates an artificial increase in the vertical length of the lower eyelid.

The musculature of the face is also subject to the aging process. The arcus marginalis of the lower eyelid divides the orbital region and the midface. It is formed by the orbital septum and a thin fascia of the deep portion of the orbicularis oculi inserted at the inferior orbital rim.

With aging, this structure becomes loose and weak and slides downward, further emphasizing the changes of the aging face.

The muscles of the orbitofrontal area have a fundamental importance in determining brow position. The frontal muscle terminates abruptly along the superior temporal line (the crest of the temporal bone); it is an extension of the galea aponeurotica, beginning at the level of hairline implantation and extending through the supraorbital skin. Its function is to elevate the brows. The brow is suspended by the frontal muscle only in its medial two thirds. Because of that anatomic aspect, the descent of the tail of the brow is usually more evident than in the head and body. Clinically, the descent of the brow tissues in the temporal region contributes to the tired or sad facial appearance often associated with aging. The temporal area and lateral periorbital

area can also be considered to be a continuation of the middle third of the face and equally responsible for the anatomic manifestations of the aging face.

FACIAL ANALYSIS

Zones of the Brow and Midface

Careful patient evaluation is fundamental to achieving a good surgical result. Facial aging is nothing more than the clinical manifestation of the physiologic alterations of facial anatomy. The midface has a direct anatomic relationship with the temporal and periorbital areas. Our facial analysis consists of a detailed evaluation of the different facial zones and their structural changes from aging.

To facilitate understanding of the endoscopic anatomy of the brow and midface, we have divided the upper face and midface into surgical zones. Success with any operation for facial rejuvenation requires a basic understanding of these aesthetic zones and the anatomic structures that are affected by the aging process.

Zone One

Zone 1 comprises the temporal region, extending medially to the temporal crest, inferiorly to the supraorbital rim, and downward along the lateral orbital rim and the superior border of the zygomatic arch. The floor of zone 1 is the temporalis muscle and the deep temporal fascia, and the roof is the superficial temporal fascia and all of the other structures superficial to it. Dissection at this level is suprafascial—on top of the deep temporal fascia and below the temporal parietal fascia.

Zone Two

Zone 2 is limited laterally by the two temporal crests, inferiorly by the supraorbital rims and nose, and superiorly to the level of the incisions. Dissection in zone 2 is subperiosteal, keeping the galea and the skin above intact. During midface surgery, the surgeon must connect zones 1 and 2 by releasing the areolar tissue at the level of the temporal crest.

Zone Three

Zone 3 comprises the lateral and inferior orbital rim, malar bone, and the premaxilla. Dissection is subperiosteal, under the malar fat pad. The infraorbital rim is often visualized in the medialmost aspect of the dissected pocket.

Zone 3 also incorporates the inferior eyelid, which we do not consider to be part of the midface.

Transitions

Understanding the transition between zones 1 and 3 and their anatomic structures is critical for safe and precise dissection in the midface. The transition between zones 1 and 3 is outlined by the sentinel veins, the medial temporal zygomatic nerve, the lateral temporal zygomatic nerve, and the lateral temporal zygomatic veins and artery. It is essential to preserve these cutaneous nerves and avoid numbness over this area of dissection.

Indications and Contraindications

Clinical indications for midfacial lifting include the following:

- Accentuation of the nasolabial grooves
- Ptosis of the corners of the mouth
- Ptosis of the lateral corner of the eyelids
- Sliding of the malar bags
- Deepening of the orbital rims
- Loss of the projection (flattening) of the malar area
- Accentuated nasojugal grooves
- Ptosis of the tail of the brows
- Dynamic periorbital wrinkles

Contraindications for endoscopic treatment of the midface include the following:

- Prominent malar bone that compensates for midface ptosis
- Lack of adequate soft tissue volume to restore midface contour
- Need for full facial rejuvenation; this category of patients can undergo midface rejuvenation without the need for a separate endoscopic procedure
- Other medical contraindications

Preoperative Assessment

Preoperative evaluation includes questions about anamnesis, current pathologies, and medications—specifically ones that change platelet adhesion, such as aspirin, ginkgo biloba, and antiinflammatory drugs. The requested preoperative exams include the following:

- Complete blood cell count
- Coagulation function assay
- Glycemia testing
- Creatinine levels and clearance
- Electrocardiogram
- Chest radiographs

Planning

Pertinent Instruments

The following instruments are of particular importance for endoscopic midfacial rejuvenation:

- Subperiosteal hockey-stick elevators
- Fixation devices
 - Casagrande needle
 - Endotine device

Hockey-stick elevators

Casagrande needle

Basic surgical instrumentation for facial endoscopic surgery

Endotine device

Operative Technique

Markings

The midface is a small area of the face, but it represents a very important aesthetic unit. Anatomically, it is delimited superiorly by the inferior eyelid, medially by the nasofacial angle, laterally by the pretragal area and sideburn, and inferiorly by the nasolabial groove. The three zones of dissection should be outlined at this point. Endoscopic midface rejuvenation can be combined with an endoscopic brow lift (zones 1, 2, and 3) or performed as an isolated procedure (zones 1 and 3). The scalp and temporal areas are prepared and marked.

The deep branch of the supraorbital nerve is an important landmark. Its trajectory should be outlined during marking to avoid incisions in this area, which can cause paresthesia in the anterior scalp.

The following landmarks are marked for endoscopic treatment of the midface:

The inferior orbital rim and zygomatic arch

The nasolabial folds

Point A at 3 cm lateral to the lateral orbital rim at the level of the superior zygomatic arch

A line communicating the distal third of the nasolabial fold to define the area of subperiosteal dissection of the midface, which is anatomically defined superiorly by the lower eyelid, medially by the nasofacial angle, laterally by the pretragal area and sideburn, and inferiorly by the nasolabial fold

The anterior temporal line (a periosteal fold that separates the frontal from the temporal area)

A line from the inferior earlobe to the lateral corner of the lateral brow to outline the trajectory of the temporal branch of the facial nerve

A line from the superior zygomatic arch at the lateral corner of the eye to outline the transition from the temporal area to the midface (zones 1 to 3)

A line that crosses the frontal area until 2 cm above the superior orbital edge divides the frontal area in two areas

Operating Room Setup and Patient Positioning

The surgical suite must be well organized to perform an endoscopic procedure. A complete surgical plan is essential to define the patient's positioning. The imaging equipment should be at the foot of the surgical table to permit better visualization. The surgeon and the assistant should be at the head of the table.

The endotracheal tube should be tied to a tooth using dental floss and wrapped with sterile plastic so that it is visible through the entire surgical case. The microcamera cable should be long enough to permit adequate movement and should be covered with a sterilized plastic sleeve. The fiber of the cold light and the optical should be disinfected in 2% glutaraldehyde solution.

Videoendoscopic equipment (including monitor)

The patient's head should be placed on a soft head support that facilitates the bilateral mobilization. The endotracheal tube, when used, should be fastened appropriately to avoid accidents during some mobilization. The positioning of the team and the patient is very important to facilitate the procedure.

Patient Preparation

The patient's hair is tied back without shaving to allow spaces for marking the incisions in the temporal and paramedian scalp sites.

Infiltration

This procedure is done with the patient under local anesthesia and sedation. Tumescence infiltration with a local anesthetic to the temporal, forehead, and midface areas allows creation of an excellent optical cavity by providing vasoconstriction and easy dissection. General anesthesia can be used with the endotracheal tube secured to the upper teeth with dental floss. The tube is wrapped with a sterile plastic sleeve and is incorporated into the sterile field. It should be visible and readily accessible at all times and if necessary adjusted without breaking sterile technique. The eyes should be protected with ointment and shields.

We infiltrate lidocaine 2% without epinephrine for nerve blockade (supraorbital, supratrochlear, and infraorbital). An anesthetic solution contains 20 ml of 2% lidocaine without epinephrine, 20 ml of 0.5% bupivacaine without epinephrine, 1 ml epinephrine, and 160 ml of cold isotonic saline solution for a total volume of 200 ml.

Incisions

A temporal incision (*red dashed lines*) gives access to the temporal area and the mid-face. It is positioned 2 cm posterior to the hairline in a coronal direction, corresponding to a line from the lateral wing of the nose, passing through the lateral tail of the brow, and reaching the scalp.

Dissection

Dissection through the temporal incisions is carried down to the deep temporal fascia. Identifying the temporal muscle under the deep temporal fascia is useful to secure the right plane of dissection, which should be above the deep temporal fascia.

Blunt dissection continues inferiorly down to a point of resistance at the level of the supraorbital rim. At this point, the endoscope is introduced in the cavity to allow better visualization, safer dissection, and adequate hemostasis. Medially the dissection continues through the areolar tissue connecting the deep temporal fascia with the subperiosteal plane (zones 1 and 2).

The plane of dissection in this anatomic zone is under skin, fat, and the temporoparietal fascia. The temporal branch of the facial nerve is superficial to this plane of dissection. It is protected by the intermediate fascia (loose areolar tissue), the superficial temporal fat pad, and the temporoparietal fascia. The nerve is in the “roof” of the dissection. Dissection continues along the areolar plane until it reaches the supraorbital rim and superior border of the zygomatic arch.

Dissection continues below the superficial temporal fascia (temporoparietal fascia) and above the deep temporal fascia. The sentinel veins are identified and preserved among the two planes. If they are in the way of the dissection, they can be cauterized; the overlying skin should be protected. The assistant should irrigate the site when necessary to optimize the quality of the optical field.

Careful tissue elevation with the endoscope will minimize trauma to the infraorbital nerve and avoid paresthesias in the midface. Creation of a limited medial area of dissection in the transition between zones 1 and 3 will prevent harm to the temporal branch of the facial nerve by avoiding the two lateral thirds of the zygomatic arch. These branches extend from the superior pole of the parotid gland, cross the zygomatic arch under the SMAS, and then become more superficial. They perforate the superficial temporal fascia and follow an anterosuperior direction, approximately 1 cm lateral to the tail of the brow, until they reach the frontal area.

The caudal dissection along the anterior temporal line (temporal crest) encounters the temporal ligament, better known as the *fusion line*; this is where the periosteum meets the deep temporal fascia.

The next step is the dissection and release of the fusion line that continues with the release of the supraorbital rim periosteum to allow release of the brow and permit entry to zone 3 in the midface. The supraorbital nerve is identified and preserved.

If the brow is also being treated (zone 2), the supraorbital dissection continues medially until the corrugator muscle is seen. The corrugators are completely avulsed with an endoscopic grasper; the branches of the supratrochlear nerve are preserved. The assistant keeps finger pressure over the glabella to assist in the removal of the corrugator fibers and to minimize trauma to the underlying skin and the development of possible future indentations in this area.

Limited undermining into zone 2 reaches the suborbicularis ocular fat (SOOF). The SOOF is a fatty sheath located below the suborbicularis oculi muscle in the lower eyelid and is firmly attached to muscle fascia.

If the brow is not being treated and only zones 1 and 3 are to be dissected, the next step is to extend the subperiosteal dissection down into the lateral orbital rim. Careful attention to this narrow and often delicate area is needed to maximize endoscopic vision and minimize trauma to the neurovascular structures present in this transition zone.

The endoscopic temporal subperiosteal approach down to zone 3 does not interfere with the muscle innervation of the lower eyelid and thereby avoids the risk of ectropion and scleral show that can sometimes be seen with the subperiosteal approach through the inferior eyelid. This complete subperiosteal undermining of zones 1 and 3 allows an en bloc suspension of the midface tissues, permitting repositioning and restoring midface volume. The subperiosteal dissection at the level of the lateral orbital rim extends laterally to the malar bone and medially along the infraorbital rim.

The *Bichat ball* or buccal fat pad is located inferiorly and deeper to the malar bag and medial to the masseter muscle and superficial to the buccinator muscle. The branches of the facial nerve pass superficial to the Bichat ball.

Dissection continues down to the gingival groove after complete release of the orbital retaining ligament. At the gingival groove, the periosteum is thin and easily disrupted during dissection. In this region the nasolabial fold can be treated, if it is too deep, by undermining of the subcutaneous tissue around it.

The masseter muscle inserts into the zygomatic bone. It is often necessary to release some of its fibers to allow an easier dissection to facilitate insertion of the scope through the lateral orbital rim down into the midface. These fibers should be carefully avulsed or transected with the endoscopic scissors. A wider dissection in this very narrow tunnel allows better visualization of the midface cavity, more secure fixations, and decreased incidence of relapse after midface lifting with the potential for better long-term results. However, a wide midface dissection can also cause more pronounced and prolonged edema.

Once the lateral orbit rim periosteum is elevated, the endoscope can be advanced with a downward movement. Subperiosteal undermining with a hockey-stick elevator allows dissection of the inferior orbital region in a safe plane. The objective is to elevate the whole periosteum and lower eyelid and its structures to allow correction

of depressions in this area. The dissection lifts and redrapes the skin and underlying tissues. The inferior eyelid can be treated separately through a transconjunctival approach to ameliorate the herniated fat pockets. If there is skin excess, it can be treated by very conservative skin removal or laser therapy. This safe approach protects the integrity of the lower eyelid innervation. The dissection extends medially to the nasal bones. At this point the premaxilla is completely released and ready for fixation.

Fixation

Long-lasting results often depend on adequate dissection, extensive periosteal release, and appropriate fixation. Two different techniques of fixation will be presented: the direct needle fixation technique and the device fixation technique.

Direct Needle Fixation

Fixation begins after undermining is complete. With this technique, a straight, thin needle (Casagrande needle) is used, based on the principles of the Reverdin needle.

The needle is introduced through the skin at points that are marked for skin elevation. After the needle is inserted, endoscopic visualization allows direct observation of the needle penetrating the optical cavity. The needle is carefully drawn out through the temporal incision, and a nonabsorbable suture is introduced through the eye of the

needle. The needle is then passed back under the skin, and after a small trajectory through the soft tissues, is brought out again externally through the temporal incision and secured to the deep temporal fascia. At this point the suture material is removed from the needle's eye and kept attached to the soft tissues, promoting elevation and fixation. Outlining of the nerves in this region helps the surgeon to avoid any damage during this maneuver. The soft tissues are secured first. In extended endoscopic frontal lifting, there is only one point of fixation at the level of the SOOF. In endoscopic midface lifting, two, three, or more points of fixation are used: the first at the level of the malar fat pad, the second to the SOOF, and another one at the infra-orbital area. In the frontal region the fixation points are applied through the paramedian incisions. Usually the first fixation point is applied in the direction of the lateral canthus, the second at the level of the lateral brow, and the third at the hairline. Proximally, the fixation is as close as possible to the hairline and deep temporal fascia.

This fixation technique permits precise repositioning and fixation of soft tissues, with predictable outcomes. The subperiosteal dissection provides an adequate blood supply to the skin flaps and allows the simultaneous use of skin resurfacing modalities, such as lasers and chemical peels. The limitations of this technique are that it relies on suture suspension only, may result in minor asymmetry because of different vectors for fixation, and involves a long learning curve.

This 50-year-old patient requested full facial rejuvenation. She underwent endoscopic suspension of the frontal region and midface with a Casagrande needle and suture technique, with fixation to the temporal fascia. She also had a cervical lift, treatment of zones 1 and 3, and a SMASectomy, as described by Baker.

Device Fixation Technique

Since 2003 I have been using the Endotine midface device (Coapt Systems, Palo Alto, CA). It is now my preferred method of suspension and fixation for malar fat pad elevation. The surgical technique for dissection is the same as previously described.

The Endotine midface device has five prongs or tines that will engage the soft tissues and suspend and secure them in position.

A deployment system protects the implant during insertion, and deployment is achieved with a simple trigger release to engage tines to soft tissue. Digital pressure engages the tines.

Once the soft tissue is engaged, the insertion tool is removed through the temporal incision.

Tension is applied to the anchoring leash to achieve the desired elevation. The leash is then sutured to the temporal fascia and the excess leash is trimmed.

This easy, step-by-step midface suspension-fixation device enhances soft tissue fixation, provides simple adjustability for optimal elevation and projection, and maintains mechanical fixation until biologic fixation is adequate. The five tines provide multiple points of contact for secure soft tissue fixation. The elevation forces are evenly distributed over a wide area, eliminating skin irregularities. Insertion and deployment are readily accomplished through the temporal incision. Implant palpability is minimal, and reabsorption starts at 6 months. The Endotine midface fixation technique offers several advantages:

- It avoids an intraoral incision.

- It eliminates sutures.

- The deployment is simple, secure, and offers multipoint fixation.

- The device is bioabsorbable.

- The leash fixation mechanism provides fast and simple adjustability for optimal control of the elevation and volume of the midface.

Tissue glue is sprayed in the dissected pocket to decrease swelling and bruising by acting as a sealant on the lymphatic drainage system.

Closure

The scalp is closed in the temporal area in two planes: one reattaching the scalp to the temporal fascia and the other closing the dermis and the skin, both using absorbable sutures. The hair and scalp are shampooed, then the patient is extubated and taken to the recovery room.

Postoperative Care

During the immediate postoperative period, the position of the patient's head should be watched carefully to maintain the airway. In the anesthetic recovery room, the headboard should remain elevated to 30 degrees to avoid excessive facial edema. The patient's blood pressure must be carefully monitored to avoid bleeding and hematomas. Ice bags can be used on the surgical areas. We also supply a splint on the undermined areas for 5 days. The patient is allowed to shower from the first postoperative day. Analgesia is accomplished with the use of an oral analgesic. Antibiotics are used for only 24 hours. Lymphatic drainage massage (48 to 72 hours postoperatively) promotes opening of the lymphatic channels with decreased swelling, less discomfort, and improved appearance in the early postoperative period.

Results

This 49-year-old patient underwent endoscopic lifting of the frontal region and mid-face with fixation, using the Casagrande technique. She also had a cervicoplasty combined with a SMASectomy, superficial and deep chemical peels, and a combined rhinoplasty. She is shown 1 year postoperatively.

This 45-year-old woman was seen in consultation for midface rejuvenation. She was treated with an endoscopic brow and midface lift using the temporal incision only and Endotine devices for fixation. Fibrin glue was sprayed in the midface pocket to minimize swelling and bruising. Lateral and oblique views at 1 year after surgery show rejuvenation of the midface area with elevation of the malar fat pad, improvement of the tear trough, and softening of the nasolabial folds.

This 39-year-old woman requested forehead and midface rejuvenation. She underwent a brow and midface lift in which the endoscopic technique was used, with a temporal incision only. The fixation of the brow lift was completed using permanent sutures from dermis to deep temporal fascia under the temporal incisions and Endotine fixation devices for the paramedian incisions. The midface elevation was obtained by using Endotines. Fibrin glue was sprayed in both dissected pockets to seal the tissues, minimize bleeding, and decrease early postoperative swelling.

This 52-year-old woman requested facial rejuvenation. She was a candidate for full-face and forehead rejuvenation with a brow and face lift. However, she did not want to have a face lift at this time to avoid the preauricular scars. She underwent a forehead and midface rejuvenation with an endoscopic technique through a temporal incision, avoiding any visible scars. The 1-year postoperative views demonstrate improvement in the forehead wrinkles, brow position and symmetry, and periocular and midface rejuvenation. Midface suspension also softened the nasolabial folds and decreased obvious jowling. Although a face lift would have provided a better solution for the lower face, this procedure employed a combination of minimally invasive procedures to meet the patient's expectations.

This 49-year-old patient wished to improve her facial appearance, especially her midface and neck. She underwent surgical rejuvenation of the entire face, with endoscopic frontal and midface suspension with fixation to the deep temporal fascia with the use of 3-0 and 4-0 nylon sutures. She also had treatment of the cervical region and a SMASectomy.

Complications

The most common complications are temporary supraorbital and supratrochlear nerve paresthesia caused by pocket dissection and stretching of the tissues. They usually last 2 to 3 weeks, are manifested frequently as numbness or local itching, and recover spontaneously.

This 45-year-old woman was seen in consultation for forehead rejuvenation. She underwent endoscopic forehead rejuvenation and experienced temporary paralysis of the right temporal branch of the facial nerve. She recovered completely after 120 days. Paresthesias resulting from a lesion of the temporal branch of the facial nerve are extremely rare. The treatment is observation and reassurance for 3 to 6 months, time required for spontaneous resolution.

Persistent edema and ecchymosis can also occur, and patients should be instructed to avoid sun exposure during this period. Hematomas can be avoided with good surgical technique, careful hemostasis, control of blood pressure during surgery, and a smooth recovery. Treatment for expansive hematomas consists of immediate surgical evacuation and drainage.

Brow and midface asymmetries can occur. They can be related to dissecting pockets differently, asymmetrical or inadequate lifting in one or both sides, and/or excess of facial muscular action immediately after surgery. Sometimes surgical revision is necessary to correct the resulting asymmetry.

Clinical Caveats

In an endoscopic midface lift, during the dissection from the temporal region to the lateral orbital rim and midface (the zone of transition), it is critically important to preserve the nerve structures to avoid numbness in the cheek area.

If necessary, the sentinel veins can be cauterized for better dissection and easier instrument manipulation in the transition zone between the temporal region and the midface.

Subperiosteal elevation at the level of the lateral orbital rim is the key to facilitating safe undermining of the midface.

Release of masseter attachments to the malar bone facilitates dissection and improves the surgeon's ability to slide the scope along the narrow tunnel in the lateral orbital rim to visualize the midface structures.

Fixation with an Endotine device is quick, safe, and reliable and does not produce the asymmetry seen with some suture fixation.

Fibrin glue can decrease the amount of swelling, discomfort, and bruising when sprayed in the midface pocket before fixation.

Intraoral incisions can be used to reinforce the fixation if necessary.

It is important to preserve the integrity of and avoid trauma to the inferior orbital nerve to prevent paresthesias.

Patients should be informed that swelling may be present for 3 to 4 weeks and numbness for 6 to 8 weeks.

Endoscopic midface lifting does not treat jowling and aging of the neck—it does not replace a face lift.

Annotated Bibliography

Casagrande C, Saltz R, Chem R, et al. Direct needle fixation in endoscopic facial rejuvenation. *Aesthet Surg J* 20:361-367, 2000.

This study examines the efficacy of endoscopic facial rejuvenation with direct transcutaneous needle fixation. In a series of 50 patients, the authors found that subperiosteal lifting with direct needle fixation allows more precise repositioning of the inferior, peri-orbital, and frontal regions. In 30 patients undergoing additional treatment for the midface, this technique eliminated the need for midface intraoral and/or infraciliary incisions. The authors conclude that endoscopic facial rejuvenation through the use of direct needle fixation provides safe and aesthetically pleasing results with a high level of patient satisfaction at 24 months' postoperative follow-up.

de la Fuente A, Santamaria AB. Facial rejuvenation: a combined conventional and endoscopic assisted lift. *Aesthetic Plast Surg* 20:471-479, 1996.

This article describes the authors' personal approach for facial rejuvenation combining conventional and endoscopic procedures. For a forehead lift, the authors use an endoscopic assisted technique, as they find this minimally invasive technique less traumatic and time consuming; it allows a greater range of possibilities for individual needs because it limits the incision and dissection to the required areas and has a higher level of acceptance by the patients. It is also a good complement to a conventional face lift.

Saltz R. Endoscopic temporal incision only midface lift is enhanced by Endotine technique. *Aesthetic Surg J* 25:80-83, 2005.

The Endotine midface technique, through an endoscopic temporal incision only approach, is the author's preferred method of malar fat pad suspension and fixation. The bioabsorbable Endotine device avoids an intraoral incision, eliminates sutures, offers multipoint fixation, and the leash fixation mechanism provides fast and simple adjustability for optimal control of midface elevation and volume.

CHAPTER 39

Alloplastic Facial Contouring

EDWARD O. TERINO

Through the ages, mankind has acknowledged that perceived beauty bestows admiration and power to its possessor. Although standards of beauty change from century to century and generation to generation, the effects that beauty has on those who both perceive it as well as on those who possess it are profound. Facial beauty represents an even more desirable goal, because all communication with others is directed from the eyes and face. The rest of the body, while it may be eloquent in its movements, is camouflaged with clothing most of the time.

Standards of facial beauty have always been associated with the face's anatomic contours. These contours exist as a result of the location, volume, and size of the facial soft tissues and their relationship to the three-dimensional architecture of the underlying facial skeleton. During some eras, roundness and fullness of facial soft tissues were the aesthetic ideal of artists, whereas in other periods more defined and dramatic skeletal contours in the malar and jawline regions were considered most attractive.

During the Renaissance, many artists depicted the ideal female face as heart shaped, with a weak lower face, chin, and mandibular contours. In contrast, contemporary standards of female beauty embody stronger structural contours. Today's women seeking aesthetic plastic surgery request jawlines with more anterior projection, a wider midlateral region, and stronger definition of the posterolateral angle. Malar-midface cheek contours cited as ideal are also strong and defined.

Facial aesthetics is important to today's patients, for whom the idea of surgical alterations to improve attractiveness has become almost a commonplace. The sculptural shape of faces has been known by artists from time immemorial; when plastic surgeons describe a face as *sculptural*, we are referring to its three-dimensional form, including its many integral parts, whose volumes and masses interrelate through juxtaposition. The location of these elements and their relative size and shape constitute what plastic surgeons call *facial contours*. Therefore facial contouring surgery refers to the art of manipulating specific anatomic features in specific locations by working with the skeletal foundation and soft tissues to alter facial topography to either create or enhance facial attractiveness. The skeletal foundation lends definition and structure to the face. Our culture considers such definition attractive or beautiful in youth and even more so during the aging process. The shape of the facial skeleton determines the contours of the overlying soft tissues. Thus skeletal augmentation with alloplastic materials allows plastic surgeons to sculpture faces three-dimensionally.

Autologous soft tissue manipulations and injectable fillers add versatility to the arsenal of aesthetic plastic surgeons; however, I think the results with these materials are less predictable and less precise than with alloplastic contouring. Structural fat grafting techniques are discussed in Chapter 13.

The Future Interrelationship Between Alloplastic Facial Implant Volumization and Injectable Fillers

To the knowledgeable surgeon who is experienced in enhancing facial volume and who has become comfortable with creating attractive facial contours by using implants, the mention of temporary injectable fillers may engender a response equivalent to the negative attitude of trained craniofacial and oromaxillary surgeons toward using alloplastic facial implants. The time-honored tradition in plastic reconstructive surgery has been to use autologous materials for reconstructing facial skeletal injuries, deformities, deficiencies, and disfigurements.

My development of alloplastic skeletal alterations for both aesthetic and reconstructive purposes, which began 35 years ago, has taken many years to gain acceptance by traditional orthognathic, craniofacial, and oromaxillary surgeons, who prefer bone, bone substitutes, and rigidly fixed materials such as Medpor and hydroxyapatite in the face. However, such materials have had a persistent history of causing infection, palpable and visible deformities, and difficulties with removal and exchangeability. Silicone rubber implants have enjoyed the true test of time and have persisted for more than 40 years because of their significant advantages.

Alloplastic facial contouring surgeons fully appreciate the inherent necessity of creating skeletal structural integrity that provides the foundation for either minor or quite dramatic and significant improvements in facial balance to create aesthetic attractiveness or beauty. They also appreciate the value of the permanent, precise dimensional qualities of these implants, which can be easily removed, modified, exchanged, or eliminated according to the patient's and the doctor's desires.

The technical simplicity with which facial implants can be routinely inserted can be thought of as equivalent to surgical interns learning their first hernia, hemorrhoid, or varicose vein operations. The only difference is that the surgeon requires an artistic perception and precise understanding of patients' anatomic needs and must know how to provide them alloplastically.

These procedures are far simpler than a rhytidectomy, SMAS dissection, deep plane dissection, or midface suspension. They require only the willingness and interest of the surgeon to learn this advanced unique, to master this valuable technology and to pay great attention to detail regarding patients' descriptions of their needs and endeavor to translate them into reality. The anatomic and technical concepts presented in this chapter are intended to provide a basis for learning these techniques.

In my experience, alloplastic facial structuring and volumization of faces are the most creative forms of facial aesthetic surgery. The role of today's injectable fillers can also be very valuable. Along with autologous fat transplantation to the face, injectable fillers have enjoyed much interest and extensive use. The role of fat grafting and injectable fillers in facial rejuvenation is more valuable than originally thought, because their results have become more predictable and longer lasting. The beneficial effects of a hyaluronic acid filler used in nonanimated areas of the face, such as the suborbital, malar, or midface region or the nasolabial sulcus area, can last 1 to 2 years. Moreover, there may even be some permanence to these fillers, because there have been some reports that their results persist for an extended period.

However, this remains an underresearched enigma. Although there are experts in fat contouring who show excellent permanent results, the process is very technique dependent: a number of plastic surgeons have found that the fat may partially or totally resorb, depending on circumstances. When transplanted fat persists, it sometimes results in unnatural-looking contours, bumps, and swellings that may be difficult to correct. When one also considers that an increase in weight produces an expansion of the transplanted fat in the face, it seems that the indications for fat transplantation should be carefully defined, and it should be used sparingly when surgeons are trying to provide long-term or permanent volume changes for their patients.

However, injectable fillers provide an exciting adjunct when combined with alloplastic facial structuring and volumization. They can be used to modify and improve the areas over, around, and near the basic foundation structure of the implants, enabling the surgeon to refine the desired aesthetic contours.

This 62-year-old woman had marked midfacial atrophy 20 years after inappropriately shaped implants were inserted by another surgeon (*left*). We replaced the implants with implants of the correct size and shape (*right*) and used injectable HA fillers to soften the contours around the implants and to fill the lower submalar mid-face region. The patient is seen 3 years postoperatively.

This 54-year-old woman had acne that had caused midfacial subcutaneous atrophy, and incorrectly shaped malar implants had been placed by another surgeon 12 years earlier (*left*). She is seen (*right*) 1 year after soft tissue volumization in the submalar midface to soften contours, and the malar implants were replaced to improve her cheek shape.

When HA fillers are used, the surgeon is able to reverse, alter, or modify unsatisfactory contours with hyaluronidase, adding another beneficial dimension to the use of semipermanent fillers. When permanent alloplastic implant facial foundations have already been built by the alloplastic surgeon, these fillers are used to augment and refine contours with greater precision.

Advantages and Disadvantages

The advantages of alloplastic augmentation of the facial skeleton are many:

Such procedures provide volume, mass, and shape to the various natural promontories of the face. The most important of these are the malar-midface and jawline-premandibular regions. The nose is a third major promontory. Great aesthetic advantage derives from augmenting or diminishing its volume. However, alloplastic augmentation of the nose is still very controversial.

Alloplastic materials do not require harvesting operations on other areas of the body.

The operations tend to be relatively rapid.

Placement under the periosteum and directly on bone produces rapid immobilization by surrounding fibrotic capsule formation.

Depending on the material used, the biologic compatibility of the host to resist rejection and infection is very high.

I favor silicone rubber, because any surrounding infections can be resolved in nearly all cases without the need to remove the implant. Administering antibiotics and placing drains will abolish infection around such implants as long as they are nonporous. If infection occurs, porous materials such as Gore-Tex, hydroxyapatite, and Medpor (Porex Surgical Group, Atlanta, GA) may have to be removed, because infectious processes can lodge within the interstices of these nonsmooth materials and challenge the body's defenses.

Another major advantage of alloplastic facial augmentation, especially when using a smooth, flexible material such as silicone rubber, is that it is easily removable, reversible, and changeable. Silicone rubber implants are very flexible and can be introduced and removed through small incisions.

Although it is true that removal of large implants from the central chin region may produce soft tissue ptosis of the central chin mound, this problem is much less likely to happen when introduction of the implant does not transect the mentalis muscle in a horizontal fashion and the dissection is performed vertically through the midline pillars of the muscle. In a rare case, a patient may request removal of a mandibular angle implant or malar-midface implant. In my series, no cosmetic or functional problem has ever resulted from removal.

The major disadvantages of the use of alloplastic materials are several:

Severe infection is possible, especially with porous materials, which become infiltrated with fibrotic ingrowth that complicates ready removal.

Contour abnormalities of an unattractive or even disfiguring nature can occur when implants do not have the proper shape, size, and positioning.

Damage to facial nerves and musculature is possible from excessive and inappropriate trauma during dissections to introduce or remove the implant.

Indications and Contraindications

Good indications for alloplastic facial augmentation are determined by relative or absolute deficiencies of contour volumes in various anatomic regions resulting from heredity, aging, or trauma from accidents, surgeries, or ablation. Contraindications exist when the overlying soft tissue coverage is severely deficient (as in severe HIV subcutaneous atrophy) or in volume deficiencies in areas of the face that do not have a stable skeletal base, such as the orbital and oral apertures.

I think that any area of the facial skeleton can be successfully contoured with alloplastic implants if they have an anatomically correct design and are placed appropriately.

Optimal implant designs must include a posterior surface that contours to the facial skeleton to provide secure contact and fibrotic immobilization. The margins of the implants must be finely tapered to eliminate palpability. There should be no fenestrations in the implant to allow penetration or fixation with fibrotic scar tissue during the healing process; this makes implants difficult and dangerous to remove. In the vast majority of cases, skeletal fixation using hardware is not necessary and may make removal complicated and risky for a novice surgeon. When desired or indicated in a specific patient situation, customized implants can be manufactured rapidly by extracting data from CT scans and skeletal radiographs (Accuscan, Implants Corporation, Ventura, CA).

Basic Concepts of Facial Aesthetic Contouring

Indications for alloplastic facial contouring arise from considerations of facial aesthetics. An artist is one who perceives natural beauty and develops techniques to imitate it. Artistic perception varies from artist to artist, patient to patient, and surgeon to surgeon. However, there are common denominators in facial form and structure that are perceived by the majority and dictate what is ultimately highly desirable today.

Even the casual observer easily notices the progressive, shrinking, atrophic quality of soft tissue substance in the faces of both men and women. This quality has often been described as the older, tired look of aging rather than the beauty of youthful maturity. This deterioration of the more ample and youthful quality of a face may be observed as early as a person's mid to late twenties and may rapidly proceed into the thirties and early forties.

It is also commonly acknowledged that in individuals with an excellent underlying skeletal foundation, as aging progresses the soft tissues shrink, and the bony prominences show more definition in the face. For some individuals, this definition actually enhances their beauty, whereas in others it unattractively emphasizes the atrophy of the overlying soft tissue. This frequently produces a negative effect that emphasizes the loss of youthful beauty.

Facial beauty relates fundamentally to a harmony and balance of various parts of facial anatomy. Therefore soft tissue substance as well as skeletal structure constitute the common denominators that determine the three-dimensional aesthetic form and shape of faces culturally recognized as attractive or beautiful.

This 58-year-old patient's face lacked balance. To correct this problem, she underwent an upper midface suspension (suborbital mimetic muscle elevation, or SOMME lift), malar augmentation in zone 1 and submalar zone 5 (SM5) with medium 3 mm malar shells. She also had palpebral shape contouring with a lateral canthal sling and revision rhinoplasty. Her lips were augmented with AlloDerm and her chin was augmented with a Terino extended anatomic large implant (Implantech). She is shown 12 months postoperatively.

The major elements of facial volume and mass are four promontories: the chin and jawline, the nose, the malar-zygomatic cheek prominence, and the forehead and supraorbital volumes. Secondary considerations are the temple contours, the premaxilla, and the suborbital region. These areas contribute more subtly but are important nuances to overall aesthetic facial balance. Tertiary contour considerations involve small increases or decreases in soft tissue volumes of the face. These exist:

- Along the jawline as jowls

- Within the perioral nasolabial region as creases and folds

- In the suborbital tear trough valley as hollowness

- Around the central perinasal premaxilla as a retrusion or protrusion

Contours in these areas also have major relevance to facial form and balance. It is the interplay between the topographic soft tissue collections and the underlying skeletal promontories that architecturally determine the contours that are perceived as facial harmony, balance, and beauty.

There are three major architectural aesthetic facial segments: upper, midface, and lower. The fundamental principle of facial balance is that a diminution or enhancement of volume (size) in one facial segment directly and inversely affects the aesthetic impact on the others. This principle applies equally to all of the primary, secondary, and tertiary volume/mass contour subunits.

Although large volume/mass changes are the most significant in matters of facial balance, even minor alterations of the subunits are equally important to observe and understand. Augmenting the nasolabial sulcus, the suborbital regions, the glabella, and other more minor subcutaneous contours has a major visual impact on facial aesthetic balance and attractiveness.

Significant aesthetic improvement is possible only when all three facial segments are evaluated precisely and comprehensively for possible simultaneous alteration. Alloplastic augmentation permits the surgeon to adjust both the major and minor promontories with equal ease and predictability, subtly or dramatically. Modifying facial contours involves three-dimensional change, whereas traditional face-lifting procedures are severely limited because of their more two-dimensional nature.

Recent suspension techniques of the upper facial segment (brow and forehead) as well as the malar-midface segment significantly complement the three-dimensional changes that provide alloplastic regional volume enhancement when performed alone. Nonetheless, only with alloplastic techniques can permanent, precise, and aesthetically pleasing changes in facial contour be produced.

Twenty years earlier, this 46-year-old woman underwent orthognathic surgery for prognathism. Fifteen years ago, she underwent malar augmentation in zone 1 and SM5 with large malar shells; she also had rhinoplasty. She is shown 1 year after undergoing upper midface suspension, a lateral canthal sling, palpebral contouring, lip augmentation with AlloDerm, and chin augmentation with extended anatomic medium and mandibular angle implants, 8 mm on the left and 10 mm on the right.

Patients with round, full, fleshy facial contours, an abundance of subcutaneous fat, and substantial muscle bulk are limited in their options when they desire a lean face that is well defined in the malar and chin-jawline regions. However, with alloplastic augmentation, full-faced patients can enjoy modest but often significant improvements to help them achieve their goal of a more sculpted face.

This 44-year-old man underwent revision rhinoplasty with conchal cartilage dorsal augmentation, as well as malar augmentation with extra-large malar shells and a large square I chin implant (8 mm projection). He is shown 2 years postoperatively with more definition to his chin-jawline and malar regions.

At equal disadvantage are extremely lean-faced individuals with a vertically long and horizontally narrow skeletal architecture and who may have extreme volume-shape weakness of the malar-maxillary or chin-mandible skeleton. These patients frequently have extremely prominent nasal contours. Although miracles cannot be accomplished, modest and often significant improvements can be achieved by rearranging adjacent proportions within their facial aesthetic segments by employing alloplastic onlay techniques in the midface or mandibular regions, with or without rhinoplasty.

Pertinent Anatomy

Understanding the fundamentals of aesthetic facial form and balance is critical for applying technical alterations to the facial skeleton successfully and predictably, without complications. Thus it is essential that surgeons adopt a specific method for analyzing faces that defines anatomic zones as well as any aesthetic segmental deficiencies of volume and mass. Relating this data about a patient's anatomy to specific goals in facial form permits surgeons to execute alloplastic contouring with excellence and precision.

Conceptualizing the anatomy of facial form into aesthetic units and anatomic zones enables surgeons to determine which areas of the premandibular, malar, and mid-face region will respond well to augmentation and produce contour changes that have visual impact, as well as emotional impact for the patient. These anatomic zones are few, but when augmented properly, each produces a different appearance.

Although the three major aesthetic segmental units of the face—upper, middle, and lower—have been described as equal thirds, the lower third jawline aesthetic unit is often smaller, both horizontally and vertically. This deficiency of the entire lower third of the face can make the nose appear too strong and overbearing. True aesthetic deficiencies in the malar-midface region often go undetected when there is a weak lower jawline segment.

This 37-year-old man with a weak lower jawline underwent rhinoplasty, chin augmentation with a square I extended extra-large anatomic implant (9 mm projection), submental-submandibular liposuction, and platysma plication to correct the deficiency and improve his profile. He is shown 13 months postoperatively.

When the lower facial segment is equal to the other two aesthetic units of the face, a malar-midface deficiency is more obvious, and many noses do not seem prominent but instead appear to be in balance with the rest of the face.

Examples of aesthetic balancing: increasing a weak lower jawline segment reduces the prominent appearance of the nose. This 39-year-old man had a malar-midface deficiency. He did not wish to have nasal contouring surgery. He underwent chin augmentation with insertion of a large square I implant (6 mm projection) to correct his deficit. He is shown 11 months postoperatively.

This 65-year-old woman underwent a standard rhytidectomy, SMAS plication, platysma plication, and insertion of an extended anatomic implant with a 6 mm projection. Seen 9 months postoperatively, she has a more balanced face.

Anatomic Zonal Analysis of the Malar-Midface Region

The midface aesthetic segment comprises the entire zygomatic-maxillary complex. The *malar space* is therefore the region on the facial skeleton that when augmented appropriately produces a beneficial aesthetic change in the contour of the midface-cheek segment.

The malar space can be seen as containing five distinct anatomic zones. Zone 1 is the largest subspace and includes the major portion of the malar bone. It extends from the infraorbital foramen to include the first third of the zygomatic arch and continues inferiorly to the lower border of the malar bone. A volume expansion of 4 to 5 mm in this zone increases the contour only in the upper portion of the cheek; this effect is often not suited to creating the desired softness of feminine facial form. An implant in zone 1 may appear too strong and skeletal. A 3 mm volume expansion is considerably more subtle, especially when combined with midface suspension techniques. However, augmentation of zone 1 by 4 to 5 mm is frequently useful in men to create a strong, masculine, sculptured appearance.

This 33-year-old woman presented with previously placed malar augmentation that she felt was too prominent. To correct this problem, she had secondary malar augmentation with large malar shells in a submalar SMS location. She is shown 10 months postoperatively.

Zone 2 has less aesthetic significance. It comprises the middle third of the zygomatic arch. Volume enhancement in this zone, especially in combination with zone 1, accents the cheekbone laterally, creating a broader dimension to the upper third of the face. It is therefore useful in improving the appearance of patients with a narrow upper face or a *long-face syndrome*. This 36-year-old woman demonstrates how a malar implant extending into zone 2 of the zygomatic arch will broaden the upper midface.

Zone 3, the paranasal region, is medial to the infraorbital foramen and nerve. A deficiency in this suborbital region can create a hollow “valley” appearance called a *jugal-malar sulcus* or *tear trough*. Alloplastic implants have been specifically designed for this anatomic zone. Releasing the origins of the orbicularis oculi muscle from the medial orbit is necessary to specifically improve this suborbital hollow appearance. Because of the thin nature of the skin and subcutaneous tissues over zone 3, any alloplastic implant or transplanted tissue must be perfectly shaped and tapered to ensure invisibility.

This 37-year-old man presented with maxillary suborbital deficiency and brow ptosis. He underwent an upper midface suspension (SOMME lift), a lateral canthal sling, and palpebral shape contouring. He also had large extended malar mandibular implants (12 mm) inserted bilaterally and a medium square I chin implant (6 mm projection) placed. He is shown 1 year postoperatively.

The infraorbital nerve is more sensitive to trauma than the mental nerve is; dissection around it must be gentle to prevent prolonged, disabling symptoms. Extended malar suborbital implants that comprehensively augment zones 1, 2, and 3 are useful for treating people with a hereditary infraorbital maxillary bone deficiency called *negative-vector polar bear syndrome*.

Zone 4 overlies the posterior third of the zygomatic arch. Volume enhancement in this area is never necessary and would produce an unnatural appearance. Inappropriate dissection in this zone as well as in zone 2 could injure either the capsule of the temporomandibular joint or the zygomaticotemporal branches of the facial nerve. Such injuries can produce edema, pain, temporary dysfunction of the temporomandibular joint, and/or weakness of eyebrow elevation. These conditions are rare and usually temporary.

Zone 5 consists of the submalar zonal triangle. This region of the midface is the most significant for augmentation, requiring the most frequent use of midface implants in both older and younger patients. Augmentation in this area extends midfacial fullness down from the malar bone itself, creating a rounder, fuller, “apple cheek” contour. Submalar zone 5 (SM5) is defined anatomically as follows. The masseter muscle and its overlying tendinous fascia are posterior; more medially, the border of the masseter muscle is adjacent to the canine fossa of the maxilla. These structures serve as the floor on which implants are placed. Its anterior soft tissue roof consists of the overlying zygomaticus muscle groups, their origins and innervations, and the submuscular aponeurotic system (SMAS). The medial limit of the submalar triangle is adjacent to the nasolabial mound.

Effective alterations in this zone may often need to be extended up and into zone 1 to create the illusion of a larger malar bone and to imitate soft tissue volume. Sometimes an implant is indicated to augment only the submalar space. The superior boundary of submalar zone 5 is also the lower border of zone 1 and constitutes the inferior bony margin of the malar eminence.

The inferior limit of SM5 is a sulcus created below the malar zone that can be extended downward through a natural dissection plane that exists between the masseter muscle and the overlying zygomatic muscle complex. As the submalar midface dissection and augmentation are extended lower, the fullness of the midface contour created by an implant in this location is also extended downward. However, no implant can extend below the mucosa of the gingival buccal sulcus adjacent to the lateral commissure of the mouth.

This 28-year-old woman presented with facial type II submalar aesthetic volume deficiency. She had submalar augmentation with insertion of 4 mm large malar shells. She is shown 2 years postoperatively with a softened, more youthful cheek.

This 49-year-old patient had a similar aesthetic submalar deficiency. To correct her deficit she underwent rhytidectomy, nasal contouring, and had 4 mm extra-large malar shells placed in SM5. She is shown 6 months postoperatively with a rounder, fuller cheek contour.

Type III aesthetic deficiency:
prominent malar eminences plus deep submalar
recession in submalar zone 5

Soft tissue volume deficiencies in the submalar-midface region are very common. These can be inherited, or, more frequently, are the result of the natural aging process. Atrophy of submalar facial fat removes the soft, full contour of youth.

Preoperatively this 61-year-old man displayed prominent malar eminences with deep submalar recessions, a type III submalar volume deficiency; 4 mm extra-large malar shells were inserted to augment SM5. He is shown 6 months postoperatively.

In many people, midface atrophy creates a tired, drawn, haggard appearance early in the third and fourth decades of life. Restoration of soft tissue fullness in the submalar region is the most significant function of midface alloplastic augmentation to restore youthful contour.

This 47-year-old woman complained of submalar atrophy and facial laxity; she underwent a rhytidectomy and upper and lower blepharoplasties. Her chin was augmented with a large 4 mm malar shell. She is shown 10 months postoperatively with more youthful contours.

The second most frequent need for midface contouring is comprehensive augmentation of the malar-midface region, which involves both zone 1 and SM5. A large shell that augments both zonal regions mimics both midfacial soft tissue volume in the lower aspect and bony augmentation in the more superior zone 1 area. The design concept of a large midface shell is to augment a generous midface area with an implant that is thinly tapered at the margins to produce volume changes without being visible or palpable and without the unnatural appearance of a localized protuberance that can be produced by smaller, traditional oval implants.

This 54-year-old woman had a relative midface volume deficiency resulting from the natural aging process. An upper midface suspension (SOMME lift) with palpebral aperture shaping, lateral temple brow contouring, submandibular liposuction, and platysma plication were performed. She also had submalar augmentation with large 4 mm malar shells and an AlloDerm lip augmentation. The result, seen 10 months postoperatively, shows natural contours and a more youthful appearance.

Zonal Anatomy of the Premandibular Jawline Aesthetic Facial Segment

Assessment of the lower third facial aesthetic segment is also necessary to comprehensively evaluate facial aesthetic balance that improves appearance. The premandibular space, when variously augmented, produces attractive changes to the shape and volume characteristics of the lower third of the face and jawline.

Within the premandibular space, four anatomic zones can be defined. These zones enable the surgeon to assess the relative volume correction needed for deficiencies in the premandibular region. Correction of such deficiencies by alloplastic implants can create specific contours for the lower face, depending on patients' individual needs and preferences.

The central mentum is the area between the mental foramina where traditional chin implants have been placed for more than 45 years. As seen in these four patients, implants placed under this central segment alone without lateral extension will produce an unattractive contour with an abnormal rounded central protuberance that accentuates the appearance of a prejowl sulcus or a valley in the area of the anterior mandibular ligament just below the mental foramen.

Traditional central implant

Contemporary anatomic implant

The floor of the central mentum zone is the surface of the central mandible, which includes the midline mental tubercle. Recent anatomic implants are contoured posteriorly to securely fit this bony contour like a glove. They provide an entirely natural-looking augmented jawline.

The midlateral zone of the mandible extends from the mental foramen posterior to the oblique line of the horizontal ramus. The anterior limit of this zone is at the mental nerve and foramen; the posterior limit is the oblique ridge of the mandible. Its superior boundary is the upper border of the horizontal mandible. The lower extent is the inferior border of the mandible. The mandibular branch of the facial nerve exits through the mental foramen 8 to 10 mm above the inferior border of the mandible. The roof of overlying soft tissues in the mid-jawline contains the platysma, SMAS, anterior facial vein and artery, and the marginal branch of the facial nerve as it crosses the mandible to enter the depressor muscles of the lower lip. Implants can augment the midlateral zone, widening the appearance of the lower jawline segment while increasing the anterior-posterior dimension of the central mentum.

I have designed a variety of implants that have differing shapes and volumes to alter the central projection and vertical length of the mandible as well as the midlateral region (midlateral zone) of the horizontal ramus.

Men are requesting jawline changes with increasing frequency. Their main area of concern is the posterolateral zone of the mandible, which includes the posterior third of the horizontal ramus extending back from the oblique line and includes the gonion of the mandible and the lower 4 cm of the ascending ramus. Its boundaries are as follows: the floor is the mandible itself; the roof is the overlying masseter muscle; the superior border is limited by the sigmoid notch of the mandible; and the posterior and inferior borders are limited by strong, fibrofascial insertions of the masseter muscle. These must be completely released to expand the space around the bony borders of the mandible. This release is necessary to allow the curved borders of the angle implants to extend around the inferior and ascending posterior mandible margins to secure these implants into position.

A mandibular angle augmentation is shown on the left, with a 3 cm intraoral incision. The illustration on the right shows degloving of the ascending ramus and inferior border of mandible.

The surgeon must avoid a traumatic dissection when releasing the masseter muscle from the bone so that neither the mandibular branch of the facial nerve (VII) nor the fragile posterior jugular veins or anterior facial vein and artery are harmed. When damaged, these vessels can bleed profusely.

The angle can be augmented to produce a strong posterior jawline contour with excellent angle definition. Implants are available that either widen this posterolateral segment in a lateral direction or extend it downward in an inferior direction. Extending it down creates a less obtuse, more acute posterior mandibular angle that gives the lower mandibular border more horizontal definition.

Exhibiting posterolateral zone deficiency of the premandibular region, this 38-year-old man requested mandibular augmentation. A 12 mm implant was inserted on the right side and a 10 mm implant on the left to correct his facial asymmetry. He is shown 1 year postoperatively with a strong posterior jawline and excellent angle definition.

The fourth and very important jawline region is the submandibular zone, which is defined as the region in the lower facial jawline-mandible aesthetic segment where volume/mass alloplastic alterations will produce variable lengthening of the vertical dimension of the face.

Traditional alloplastic chin implants do not and cannot increase the vertical height to lengthen the lower third aesthetic segment. Osteotomies with interpositional bone grafting or autologous fat transplant techniques are currently the methods chosen by most plastic surgeons to accomplish this important contour change. For the novice surgeon, orthognathic genioplasties are technically complicated, imprecise, and have significant complications (5% to 10%) such as nerve damage, asymmetries, and stepoff irregularities.

In 1986 I developed a unique extension implant to wrap around the inferior or bony region of the mandible and increase the vertical distance from the lower lip to the inferior chin. It extends 4 mm down and laterally augments the submental zone. This implant adds volume to the anterior mandibular segment and to the prejowl sulcus or marionette groove at the origin of the anterior mandibular ligament.

Implants in the submalar zone improve or correct a witch's-chin deformity and the anterior mandibular prejowl sulcus, as is seen in this 62-year-old woman. She had facial laxity resulting from aging, suborbital hollowing, and prejowl sulcus and platysmal laxity. To correct these problems, she underwent an upper midface suspension with fat transposition and palpebral aperture shaping. In addition, medium malar shell implants were inserted in lower zone 1, and extended anatomic implants with 4 mm projection were inserted in the upper SM5. A rhytidectomy with SMAS plication and platysma plication were performed during the same operation. She is shown 7 months postoperatively.

Augmentation of the submalar zone involves complete disinsertion of muscle origins along the lower mandibular border. At present submandibular implants afford only 4 mm of projection. There are times when additional projection necessitates placement of a second implant on the anterior surface of the central mentum.

Just as volume augmentation changes are specific for each zonal area of the malar-midface middle third facial segment, contour changes can be differentially produced in the lower third of the premandibular jawline.

Nasal size alterations are also frequently requested. These procedures also contribute greatly to overall aesthetic facial balance.

The correct choice of implant size and shape as well as positioning it properly are the key steps to achieving specific, predictable results.

This 27-year-old man presented with nasal deformity, lower third facial aesthetic segment deficiency, submental and submandibular lipodystrophy, and a defuse neck. He is shown 1 year after cosmetic rhinoplasty, submental-submandibular liposuction, and platysma sculpture. Submandibular augmentation with a medium vertical extension implant was also performed.

This 22-year-old patient demonstrates dramatic improvement in facial balance from malar, chin, and mandibular angle implant augmentation combined with rhinoplasty. He is shown 2 years postoperatively.

Anatomic Danger Zones

Midface

Midface problems and complications arise from too vigorous a dissection over the middle third of the zygomatic arch when the surgeon places a malar implant into zone 2 to create a broader face. The overlying facial nerve branch to the frontalis muscle may be damaged temporarily or permanently. Branches of the zygomaticus muscle groups, as well as those that extend up into the inferior lateral orbicularis muscle can be traumatized during dissection into malar zone 1 and SM5. This may result in transient or permanent lagophthalmos and an impaired ability to elevate the nasolabial area during smiling and facial animation.

Dissection in the zone 3 medial suborbital maxilla area exposes the infraorbital nerve to damage when alloplastic tear trough implants are introduced or during midface suspension techniques.

When a subperiosteal malar space is created over the lateral aspect of the orbital rim, but the dissection space is not opened inferior enough on the maxilla to permit a malar shell to be placed approximately 4 mm below the orbital rim, the implant can ride high enough to overlap the lateral rim, encroach on the orbit, and produce vertical descent of the lower eyelid or ectropion. This is particularly common when implants are introduced through the subciliary lower eyelid approach.

Premandible

During premandibular dissections, trauma to the mental nerve is common, but symptoms are usually transient. Dissecting gently along the inferior border of the mandible and sweeping upward lightly to observe and protect the mental nerve helps to avoid these symptoms.

The surgeon is able to visualize the mental nerve using a retractor and insert an implant submentally.

Dissecting and degloving the muscles along the inferior mandibular border are an absolute necessity for midlateral zone augmentation. However, during this dissection the marginal mandibular branch of the facial nerve can be injured, producing lower lateral lip dysfunction.

Unless great care is exercised during dissection in the posterolateral mandibular zone by degloving the entire posterior region of the inferior border and ascending ramus of the mandible, the jugular vessels posterior to the ascending ramus can be injured. This could create profuse, dangerous bleeding.

A forceful upward dissection into the sigmoid notch and coronoid process of the mandible can produce troublesome temporomandibular joint symptoms. These are usually transitory—less than a week in duration. Trismus is an uncommon sequela of posterior angle augmentation. In my experience, this has always been extremely short lived.

Regional Midfacial Volume Deficiencies

To determine which elements are necessary to achieve facial balance in a specific patient, the surgeon must recognize malar-midface zonal deficiencies. Although there are infinite variations in facial size, shape, and contour, there are several common midfacial types that can easily be identified for determining specific implant sizes and positioning. Several of these will be described.

Surgical Treatment Plan for Premandibular Augmentation of Regional (Zonal) Volume/Mass Deficiencies

Zone	Implant* (depends on face size)
Central mentum	Anatomic or styles I and II 4-9 mm
Posterolateral	Mandibular angle implants 8-12 mm Lateral projection
Midlateral	Lateral bars 4-6 mm Widens lateral jawline
Submandibular	Vertical extension implant 4 mm Inferior and anterior projection

*Manufactured by Implantech Corp., Ventura, CA.

Selection of Implants

Facial Type	Anatomic Augmentation Zone	Size (depends on skull size)
I	1 and 2	3 or 4 mm (occasionally 5 or 6 mm)
II	Submalar 5	4 or 5 mm (possibly a combined shell)
III	Submalar 5	5 or 6 mm (large or extra-large)
IV	1, 2, submalar 5	5 or 6 mm malar shell (large or extra-large)
V	3	Tear trough implant (small, medium, or large)
VI	Premaxilla	Various premaxilla implants Brink implant*

*Manufactured by Implantech Corp., Ventura, CA.

Type I Deficiency

Type I aesthetic deficiency:
malar hypoplasia

A facial type I deficiency consists of a relative contour weakness in the upper segment of the malar-midface region. It encompasses zones 1 and 2 over the malar bone and the medial third of the zygomatic arch. This involves either a bony or soft tissue deficiency, or both. Augmentation in these zones creates upper cheek fullness that simulates both bony and soft tissue contour.

This 39-year-old woman had a type I regional volume deficiency. She is shown 1 year after malar augmentation with 4 mm large malar shell implants in zones 1 and 2.

When a large implant is used to augment zone 2 as well as zone 1, the upper midface becomes broader, shortening the appearance of a long, narrow face, as seen in this patient. This 34-year-old woman desired more definition in malar zones 1 and 2 as well as in her mandibular angle. She also wanted aesthetic segment enhancement of the lower third of the central mentum. She had 4 mm medium malar implants inserted to augment zones 1 and 2. Her mandibular angle was augmented with 8 mm per side, and 4 mm small extended anatomic implants were placed to augment the central mentum. She is seen 1 year postoperatively.

Type II Deficiency

A type 2 regional aesthetic deficiency consists of a relative decreased volume in SM5. An implant placed here produces volume filling that imitates bone and soft tissues. Use of a large malar shell over the inferior aspect of the malar bone in zone 1 and extending down into the submalar space creates the illusion of a round, full, apple cheek. The fat atrophy that occurs with aging is corrected by placing implants in SM5.

This 55-year-old woman had facial laxity and submalar atrophy from aging. She underwent a rhytidectomy, upper and lower blepharoplasties, and SM5 augmentation with medium Terino 4 mm malar shells. She is seen 2 years postoperatively.

This 37-year-old woman had malar facial deficiency in zones 1 and 2. She underwent malar augmentation with medium Terino 4 mm malar shells. She is seen 1 year postoperatively.

This patient, 55 years old, had a type II midface volume deficiency and relative prognathism. She had adequate malar bone prominence but was specifically deficient in submalar soft tissue volume. This can create a tired, haggard look. The submalar zone ends just lateral to the nasolabial smile mound. Volume filling of this space deemphasizes the appearance of the nasolabial mound and corrects the sunken appearance in the midface to restore a fuller, more youthful appearance. Her procedures included midfacial implants, upper and lower blepharoplasties, rhytidectomy, rhinoplasty, and SM5 augmentation with medium Terino 4 mm malar shells. She is seen 6 months postoperatively.

Aging changes in this 62-year-old patient included brow ptosis, lateral face and neck laxity, and type II malar deficiency. She underwent an upper midface suspension with palpebral aperture shaping, malar augmentation of zones 1 and SM5 with a large Terino 4 mm malar shell, lower face and neck rhytidectomy, SMAS and platysma plication, and cosmetic rhinoplasty. She is seen 1 year postoperatively.

Type III Deficiency

A type III regional volume deficiency consists of a strong malar-zygomatic superstructure accompanied by an extremely deficient submalar infrastructure. When this condition is accompanied by thin skin and subcutaneum, the patient appears emaciated and sick. Fortunately, unless a person has an actual physical debility, this facial type is uncommon in the general population. Correction requires generous submalar augmentation with a large surface area midface shell with a projection thickness of 5 to 7 mm.

This 67-year-old woman had an emaciated appearance, facial atrophy, and extreme laxity of the facial skin. She desired only augmentation of the malar-midface region. A malar-midface SM5 and zone 1 augmentation was done with an extra-large Terino 5 mm malar shell. She is seen 1 year postoperatively.

Extreme type III submalar atrophy and prominent malar bones were present in this 43-year-old woman. She underwent SM5 augmentation with large Terino 4 mm malar shells. Her cheeks have a more youthful fullness 6 months after surgery.

Type IV Deficiency

A type IV face consists of extreme volume deficiency throughout the anterior maxillary region. This includes malar zones 1 and 2, the SM5 regions, and the entire orbital and paranasal zone 3 area. This deficiency seems to be more common in men than in women. It is identified by a flat-face or dish-face appearance. It has been described as the *polar bear syndrome* because of the deficiency recession of the inferior orbital rim, which contributes to a proptotic bulging appearance of the ocular globe. This is called a *negative-vector bony deficiency* of the inferior orbital rim. It may be associated with a downward or vertical descent of the lower eyelid causing sclera show.

Significant improvement in this type IV aesthetic imbalance can be achieved through placement of a comprehensive shell implant that contributes volume in all of these midface zones, including the infraorbital region. This implant also adds support to the lower eyelid and elevates it to a more attractive horizontal position.

This 35-year-old man had a negative-vector suborbital hollowness deficiency, type IV aesthetic regional volume deficiency, malar hyperplasia, and submalar maxillary deficiency. An extra-large Terino 5 mm malar shell was placed in zone 1 and SM5. He is seen 1 year postoperatively.

Lateral canthopexy techniques are often necessary to correct the descent of the lower eyelid that is common with this facial type and to prevent its worsening after malar surgery. This represents both an aesthetic and a functional correction.

Type V Deficiency

Type V aesthetic deficiency:
suborbital zone 3 and upper zone 1 deficiencies

A type V aesthetic regional deficiency involves a specific weakness of skeletal structure in the inferior orbital and medial tear trough region. This contributes to a tired, hollow appearance around the eyes following the deflation and atrophy of the peri-orbital tissues as the individual ages.

A uniquely designed tear trough implant is placed that extends from the medial canthus to the lateral orbital malar rim; this considerably improves the previously hollow appearance. Autologous tissue transplants of fat, muscle, galea, and temporalis fascia placed into this area have provided good results, but their success and the associated complication rate are still controversial. Fat grafting along the inferior orbital rim is considered by some to be advantageous. My own experience has been that autologous soft tissue grafting results in unpredictable shrinkage and may produce irregularities or yield negligible improvement.

This 42-year-old man presented with an extreme suborbital volume deficiency. This deficiency was corrected with large tear-trough implants of 5 mm projection, placed through a transconjunctival approach. He is seen 1 year postoperatively.

Over the past 5 years there has been strong interest in a subperiosteal elevation of all soft tissue layers from the maxilla followed by a suspension of them in an upward direction to provide greater volume filling in the inferior orbital rim area. This mid-face suspension can be accompanied by inferior orbital fat rearrangement over the inferior orbital rim. This is done after severing the origins of the orbicularis muscle and disrupting the arcus marginalis and underlying SOOF tissues in the medial tear trough area.

Subperiosteal midfacial suspension alone without the addition of alloplastic implants is a technique that is still new enough to require the test of time to evaluate long-term persistence of volume correction and three-dimensional improvement of the suborbital hollow appearance and malar-submalar shape.

SOMME MIDFACE SUSPENSION LIFT

The subperiosteal dissection in the SOMME midface suspension lift extends 3 to 4 cm below the lower border of the malar bone and over the masseter tendon down to the area of the buccal fat pad. This also extends to the buccal sulcus just superior to the canine tooth. The entire soft tissue mass of the cheek, which includes the zygomaticus muscles, is secured to the deep temporal fascia via a subperiosteal tunnel made along the lateral orbital rim. This elevation automatically includes the orbicularis, which adds an additional layer of support over the infraorbital bony rim, obliterating the hollow lid-cheek junction.

A midfacial implant can be chosen to fit (1) on the malar bone, (2) on the submalar zone over the masseter tendon, or (3) to be an extended tear trough implant in the midface when placed during a midface suspension procedure.

Type VI Deficiency

Type VI aesthetic deficiency:
recession in perinasal premaxillary region

A type VI midface deficiency occurs in the perinasal premaxillary region. Volume deficiency or the appearance of retrusiveness in this aspect of the skeleton is common in certain ethnic groups, especially in Asians and Indians in the Americas. It also exists as a congenital hereditary trait, which can be mild or severe and may require complicated orthognathic surgery using maxillary LeForte bony advancement techniques.

Alloplastic augmentation can improve mild to moderate premaxillary deficiency to produce significant aesthetic changes. There are several designs and sizes of silicone rubber implants that have been used successfully over the years to alter nasolabial and premaxillary relationships. Although other materials such as AlloDerm, autologous fat, Gore-Tex, collagen, and other injectable materials are used in the nasolabial and perialar sulcus, these have only resulted in temporary augmentations. Alloplastic augmentation is permanent. Type VI peripiriform and premaxillary volume deficiencies are common. They are frequently overlooked by aesthetic surgeons. They are usually of lesser magnitude than the greater volume/mass interrelationships of the malar-midface area, jawline, and nose. Therefore they do not warrant as much attention during an initial aesthetic facial contour consultation unless the patient is focused on such a deficiency.

Left: A local anesthetic is injected over the intended bed of the implant and at the preferred incision site, which is at the junction of the columella and floor of the right nostril. *Center:* The orbicularis oris muscle is split and the dissection plane established directly on bone. *Right:* The pocket is easily developed with a periosteal elevator. The edges of the piriform aperture are visualized, and the nasal vestibule is avoided.

Left: External palpation can facilitate dissection in the upper reaches of the pocket. *Right:* With an Aufricht retractor and curved hooks, the implant is inserted with a rotary motion first to the side opposite the incision.

Left: The implant can be gently overinserted on the first side to facilitate introducing its trailing edge into the incision. *Center:* The Aufricht retractor and hooks are repositioned to assist insertion through the incision. The implant is advanced back to midline. *Right:* The symmetrical position of the implant can be confirmed by direct visualization of its central notch at the nasal spine and by external and intra-oral palpation.

This 38-year-old Asian woman had a type VI regional facial deficiency with a retrusive maxilla RY volume deficiency. Correction was accomplished by the addition of a Brink small premaxillary peripiriform implant. She is seen 6 months postoperatively.

This patient, 33 years old, had a type VI severe retrusive peripiriform volume deficiency. A Brink peripiriform medium premaxillary implant was placed. One year postoperatively, the patient shows significant improvement.

Preoperative Assessment

Physical Examination

I use computer imaging as an integral part of the physical examination/consultation to provide more objective analysis of the patient's anatomic contours. The patient holds a mirror during the examination. One of the most important objectives of the consultation is to precisely identify the various asymmetries of bone and soft tissues in the patient's face; it is imperative that the patient understand the significant limitations in correcting these asymmetries.

A fundamental and critical element in a consultation is to accurately define a patient's desires and goals by asking the patient to precisely describe changes he or she hopes to achieve and in which anatomic regions. The surgeon must then be able to relate the patient's remarks to the anatomic zonal analysis data previously described.

I require patients to bring two sets of standard medical facial photos and, just as important, examples from magazines of contour ideals they want to emulate. It cannot be overemphasized that the selection and placement of implants is determined by directly comparing the anatomic zonal contours from their choice of images to the patient's own face. It is important to discuss with the patient in precise terms whether or not it is possible to achieve his or her goals, and to what degree.

Patient Education

The Consultation Process

In my practice, patient education begins with the requirement that patients who desire facial contour alterations must describe verbally, as well as in writing, the specific details of their desired contour changes. This must include their perception of their contour deficiencies. This written statement must be accompanied by standard professional photographs of the patient in five views: one frontal, left and right profile, and left and right oblique views. These facilitate analysis of their perceived contour deficiencies and are used along with photographs they choose from magazines and other sources to demonstrate the ideal they would like surgery to create. Photos of the patient at an earlier age are also requested.

This patient provided photos of herself at age 41 (*left*) and at age 50 (*right*). She was seen for consultation at age 59 with relative midfacial atrophy from aging. She desired a return of youthful fullness as well as contouring of her lower face, neck, and jowls.

An upper midface suspension was performed, with lateral temple–brow contouring. Submalar midface augmentation was also done in lower zone 1 and SM5 using a large Terino 4 mm malar shell. A lower face and neck rhytidectomy with SMAS and platysma plication was also performed. She is seen 1 year postoperatively.

The patient benefits from the use of educational tools before a face-to-face consultation with the surgeon. The Confirm Program CD on facial implants, which I prepared for the American Society of Plastic Surgery, serves as an excellent instructional tool to explain concepts of facial balance as they relate to the basic interrelationship of the three major promontories: the malar-midface, the nose and the chin-jawline. I also use other videos and photos in which I draw the malar zygomatic and pre-mandibular zones of the facial skeleton on the patient's face and demonstrate how specific positioning of various sizes and shapes of implant alters the third dimension of the midface in different ways.

Computer Imaging as a Teaching Tool

Computer imaging is an invaluable tool to assist the surgeon in explaining the possible outcomes of augmentation. It must be emphasized to the patient that while it is useful to view a simulated potential result, there is no guarantee that the result will be identical to the simulation.

In this series, the patient is shown preoperatively on the left, and a computer simulation of possible alterations is shown on the right. The lateral views demonstrate volume augmentation of the chin and diminished volume of the nose. The oblique views show the effect of augmentation of the cheeks, chin, and angle of the mandible without rhinoplasty. The frontal views demonstrate the effect of using rhinoplasty in addition to malar and chin augmentation, and angle of mandible augmentation.

Not only can changes be shown that simulate desired volume and shape alterations, but these can later be compared using side-by-side preoperative, computer-generated, and postoperative images. When this tool is used cautiously and conservatively, the surgeon can demonstrate that the final results of surgery (in the case of these two patients, 1 year postoperatively) are photographically superior to the image simulations made during the consultation.

Markings

Final planning is done on the morning of surgery before the patient is taken to the operating room or given any form of preoperative medication. The surgeon sits with the patient before the image computer and with the selected magazine photographs brought by the patient. Markings are made on the patient's face to outline the borders of the bony architecture and to designate the facial zones of the midface and premandibular regions. Similar markings can be made on the magazine photographs. The patient is then asked to identify which specific zones he or she wants altered by looking at the marked magazine photos and their own facial markings in a mirror.

These are typical markings made before augmentation surgery. The red markings indicate the supraorbital, infraorbital, and mental nerves in the malar, submalar, and chin region. The outline of the chosen implants is circumscribed as well.

Then the implant size, surface area, and projection are discussed with the patient by placing implant sizers on the patient's cheek over the skin markings of the anatomic zone or zones the patient has selected. In this way the patient assists in the decision about the zones and implant sizes most suitable for an ideal result. The implications of various sizes and thicknesses of implants and how they could be used to achieve a subtle, conservative result or a more dramatic appearance are discussed.

For this patient, malar-midface augmentation was planned. Outlining of the malar zygomatic bone and infraorbital nerve is shown, as well as measurement of the submalar zygomatic space. Measurements are used to help select the proper size implant to fit the patient's anatomy. The red marks demonstrate the planned augmentation, which in this patient will extend below the malar bone and into the top of the submalar zone to create fullness in that area.

A similar patient-doctor communication session with the computer and magazine images is used when augmenting the lower third of the face, chin, and jawline.

PREOPERATIVE PLANNING

Implant Considerations

Choice of Implant

Detailed discussions with the patient always reveal the subtleties and nuances of the specific contour results he or she anticipates. It remains for the surgeon to evaluate whether the patient's desires can be fulfilled by means of up-to-date implant augmentation techniques.

The following guidelines are suggested:

1. Implant enhancement of the upper malar/zygomatic bony region (zone 1) produces a sharp, high, angular appearance.
2. Placing the implant or choosing one that extends laterally into zone 2 widens the upper aspect of the midfacial segment.
3. Augmenting the submalar region to correct a hereditary defect or the appearance of aging (type 2 midface deficiency) produces a fuller midface in the lower aspect of the cheek below the bone.
4. Deciding whether to augment the upper malar bone aspect of the middle third aesthetic facial unit or the lower submalar soft tissue segment is the most important factor in creating a specific cheek-midface contour that meets the patient's goals.

Implant Size

The size of an implant relates to surface area and thickness. Standard 4 mm commercial shells of large or jumbo sizes are suitable to produce natural, pleasing augmentations in more than 90% of patients. Occasionally, when the patient wants a more subtle effect, 3 mm medium shells can be used. When a more dramatic effect is desired, 5 or 6 mm shells are most advisable. Large shells of 20 cm² and jumbo shells of 30 cm² are always preferable to small implants of 15 cm² or medium implants of 18 cm². A broader surface area creates subtle, invisible, and nonpalpable contours rather than a prominent, localized lump.

Implant Positioning

A subperiosteal location has proved the most desirable one because of rapid fixation of implants to the bone or underlying structures, such as the masseter muscle. Subcutaneous placement frequently results in implant mobility, because circumferential encapsulation occurs within elastic soft tissues, permitting ready movement when manually manipulated.

Fibrous ingrowth into porous materials or through implant fenestrations is completely unnecessary. When smooth implants are used, correction of a malposition simply requires that a new, accurately located space be created directly on the bone level and beneath all anatomic tissue planes, including scar tissue and previous capsules. Dissection of the space of slightly larger capacity facilitates placement of an implant without buckling, infolding of the edges, or abnormal bulging.

Facial Asymmetry

Natural facial asymmetry is universal. A form of hemifacial microsomia occurs in more than 90% of patients. On careful examination, the left and right sides of the face are usually quite different in size, shape, or volume. One side may be wider and have a greater volume of bone and soft tissue. One orbit, eyebrow, or eye complex is usually lower than the other.

Patients can be very particular and obsessed with asymmetries. Such asymmetries frequently go unnoticed before facial implant contouring. Therefore it is imperative to evaluate facial asymmetry meticulously in the preoperative consultation, noting them in the medical record, and explaining them in detail to the patient. It is also necessary to warn the patient that asymmetries will still be present to some degree following surgery, even when implants of different sizes are chosen and positioned to compensate for the variations in volume and shape that already exist.

This 42-year-old man had subtle asymmetry of his mandible-jawline for which he requested improvement. Different sizes of mandibular angle implants were used, 12 mm thick on his smaller right side and 10 mm thick on his larger left side. Malar implants were also requested. He is shown 2 years postoperatively.

In my practice, asymmetries are documented in the patient's chart by computer imaging or photographic modalities. Documentation helps to counter any postoperative criticism if the asymmetry is still apparent in the least degree to the patient.

Preoperative

Computer-generated
right-sided mirror imageComputer-generated
left-sided mirror image

This 28-year-old man had significant hereditary facial asymmetry, as demonstrated by computer imaging technology. The computer-generated images dramatically show that the right side of his face was proportionally narrow compared with the left side. The patient is shown 1 year after mandibular augmentation.

Although CT-generated computer-aided design/computer-aided manufacturing (CAD/CAM) technology can be used to create implants from customized models with asymmetrical skull anatomy, at present such an advanced method is used only for correction of the most complicated and sophisticated problems. CAD/CAM customized modeling has been used mostly for correction of posttraumatic and congenital birth defects and deformities. Such customization is time consuming and expensive, and the results are at best only moderately more successful than those obtained with standard, universally designed anatomic implants. In the past 3 years, however, approximately 1 out of 12 of my patients who consulted exclusively for facial implant contouring felt comfortable purchasing implants derived from CT CAD/CAM technology; these are molded on their posterior aspect to custom-fit a personalized skull model.

Advancements in this area of computer technology are rapidly evolving and will soon enable aesthetic plastic surgeons to correlate implant sizes and shapes with desired changes in facial form and contour.

Choosing implants to correct asymmetries is presently a matter of intuitive artistic judgment rather than of technical precision. Obviously, a thicker implant with a larger surface area is indicated for the side of the face that lacks bone and soft tissue volume. Similarly, for jawline asymmetries in the posterior mandibular and mid-lateral zones, implants that provide additional thickness of 1, 2, or 3 mm at the angles and along the horizontal ramus can be used on the deficient side of the mandible.

Perhaps the most important principle for the surgeon to remember is that minor asymmetries tend to become less noticeable within a 6-month postoperative healing period, during which relaxation of the collagenous capsular matrix around the implants allows the contours to appear softer.

Custom Designing Implants Using Three-Dimensional Computer Modeling

Any chapter on facial volumization with implants would be incomplete without a brief discussion of the latest unique and innovative techniques for custom-designed facial implants. I have been responsible for the major advances to date regarding the development of anatomic alloplastic designs for the chin, jaw, malar midface, sub-orbital maxillary area, and other regional volume deficiencies in the face. I first used these designs in 1977. My patented implant designs represent a decade of evolutionary alterations to evaluate the final contours produced by observing the resolution of the final swelling at the end of the first postoperative year.

Through years of experience, I found that the need for certain small modifications was obvious for a number of patients. With the growing popular interest in facial contour modification by means of implant volumization, current patients have become very specific and particular about the details of the contours they believe can be achieved through the modern miraculous work of aesthetic plastic surgeons.

Some patients develop unachievable expectations from having pored over glamorized articles, photographs, comments, and various media reports that indicate that many of the most attractive models and actors have achieved their structural beauty through prosthetic plastic surgery.

Thus present patient demands have stimulated sophisticated alloplastic facial surgeons to accept the challenge to meet such expectations. Custom-designed facial implants are now possible through modern CAD/CAM methods that perfectly duplicate anatomic topographic contours to form-fit implants individually to the skeleton in these more sophisticated and demanding cases.

These CAD/CAM models were generated from CT scans that precisely duplicate anatomic topographic facial skeletal contours.

Over the past 20 years, three-dimensional CAD/CAM implants have been used successfully for facial reconstructions by craniofacial and oromaxillary surgeons. Over the past 8 years, I have found good reasons to also apply this technology for regional aesthetic facial volume deficiency problems.

Although asymmetries of the face are present 100% of the time in varying degrees, when they are minor, they may go unnoticed by patients before their cosmetic surgery consultation, and if these are not brought to their attention before surgery and documented, the surgeon will surely be plagued by patient complaints after surgery about perceived malpositions, asymmetries, and postoperative deformities.

When asymmetries are more obvious, many patients come to the consultation with a specific goal to have their asymmetries corrected. Many have somehow come to believe implicitly that the aesthetic facial surgeon, especially one who performs facial implant procedures, can succeed in achieving a near-perfect result. All experienced surgeons know that nothing can be farther from the truth. In trying to accomplish symmetry over a 35-year period, I have discovered that this is rarely possible, although considerable improvements can be made through the use of different sizes and shapes of implants positioned slightly differently on the facial skeleton. Even so, today's patients demand still more precision. Therefore custom-designed fitted implants that are accurately matched to the external surface nuances of the bony facial skeleton can often provide more ideal positioning and attachment of the implants to the underlying bony prominences.

These CT scans show accurate positioning and form-fitting of multiple custom implants for a particular patient's skull (see patient on p. 1254).

This silicone rubber preliminary custom-made implant has been form-fitted based on a patient's CAD/CAM-generated mandible model.

I have also discovered that facial asymmetries are never exclusively skeletal in origin. In cases in which by good fortune surgery has resulted in perfect bony symmetry, soft tissue deficiencies of the muscle, fascia, and fat layers still persist, demonstrating that they also contribute to the asymmetries in every instance. This reality must also be emphasized to patients preoperatively.

It is not within the scope of this chapter to discuss the detailed techniques for using custom-designed facial implants. My purpose is to acquaint readers with this subject and to indicate the marvelous technologic progress in aesthetic facial contouring that exists and will continue to be developed.

All facial aesthetic surgeons are waiting for the historical moment when computer image modification of the patient's photographic image in their office can be successfully combined with a three-dimensional CT scan to provide instant individualized patient information regarding the dimensions of implants and specifics for positioning them, which will provide optimal precision results. Indeed, if equipment were available for office use that could readily manufacture such personalized implants, the ultimate dreams of an alloplastic aesthetic surgeon would be realized. Patients as well as surgeons would be grateful for the emotional security and enhanced confidence in both the surgeon and the procedures.

The details of this customized methodology can be found in the references section. For aesthetic custom design implants to be used for facial skeletal volumization, biocompatible alloplastic implant materials such as Silastic (silicone rubber) are more predictable and durable than autologous grafts. Experience as well as research with bone or cartilage autografts has confirmed that unpredictable and variable amounts of resorption occur, and harvesting the grafts carries a risk of donor site morbidity.

This 41-year-old man required multiple malar-midface and chin-mandibular angle custom-made form-fit implants, as seen on his CT scans on p. 1252.

It has also been established that it is easier to predict soft tissue displacement after direct augmentation with grafts or implants than with orthognathic procedures such as osteotomies and segmental bone repositioning. Therefore custom-designed onlay implants are a more desirable option than more extensive traditional orthognathic reconstructive surgery.

A custom-made hemimandible silicone implant is shown.

This 27-year-old woman had a congenital right hemimandibular deficiency. The markings for the surgery are shown, and she is seen 6 months after a right hemimandibular implant was placed.

Operative Technique

Patient Positioning

In all facial contouring surgery the patient is positioned supine on the operating table. General anesthesia is indicated to control the blood pressure adequately. Clonidine (0.2 mg) is given preoperatively for vagosympathetic stabilization. The systolic blood pressure is maintained by the anesthesiologist at a level of 90 to 100 mm Hg. A local anesthetic is also generously infiltrated into the tissues. The ideal anesthesia for alloplastic facial contouring is shown in the box.

Anesthesia Protocol

General Anesthesia

Maintain systolic blood pressure at 90 to 100 mm Hg
Clonidine 0.2 mg given orally preoperatively

Local Anesthesia

Lidocaine solution 0.2%
Epinephrine 1:800,000
Generous tissue infiltration into malar or premandibular space (20 to 30 ml each)

A volume of 20 ml is injected into each malar and premandibular region. The anesthesia solution should be placed beneath the periosteum. This protocol enables the surgeon to execute facial implant surgery in a nearly bloodless field.

Incision Placement

Incisions to approach the malar-midface and premandibular regions are as follows:

- Intraoral
- Lower blepharoplasty (subciliary)
- Rhytidectomy
- Transcoronal
- Transconjunctival

There are several surgical approaches for augmenting the malar-midface space. The most traditional and commonly used approach for midface augmentation is the intraoral route. A 1.5 cm incision is made only through the mucosa. The excision is extended obliquely upward over the anterior buttress of the maxilla just above the canine tooth. It is connected with another 1.5 cm horizontal incision made 1 cm above the gingival buccal sulcus that is extended posterior to the premolar tooth. The dissection is initiated onto the bone only through the lower border of the incision and always remains on the bone.

A lower blepharoplasty incision can also be used by dissecting beneath a skin muscle flap onto the lower orbital bony margin and penetrating the suborbicularis oculi fat (SOOF) layer in the lateral aspect of the orbit down to the bone. The midface zone 1 area can be dissected subperiosteally from that location.

If a rhytidectomy insertion is intended, a small penetration is made through the soft tissues over the lateral aspect of the malar bone at the junction with the zygomatic arch. This facilitates entrance into the subperiosteal malar space in an area where no major facial nerve branches are endangered.

Premandibular augmentation involves two types of incisions to:

Augment the angle of mandible

Create the central mentum space for insertion of a central implant with lateral anatomic extensions

The central mentum space can be approached from the intraoral route or with an incision in the submental crease. The submental crease incision is preferred when there is to be dissection into the neck, either to remove fat or to manipulate and tighten the platysma muscle, or both. This incision is approximately 2.5 cm in transverse length and penetrates directly down onto the lower border of the mandible. From that location a subperiosteal dissection is done laterally in both directions. The intraoral incision is a transverse mucosal incision of 2 cm only, placed 1 cm superior to the gingival labial sulcus. Next a vertical penetration is then made between the two pillars of the mentalis muscle. The mentalis muscle should never be transected, because this would produce weakening and ptosis of the central chin mound. By dissecting vertically between the muscles and then developing the subperiosteal space inferior to them, the muscular support of the soft tissues of the chin mound is maintained.

In either dissection, the mental nerve should be located and identified. It is usually situated 8 to 12 mm above the inferior border of the mandible and 2.5 to 3.5 cm from the midline of the central mandible. Extreme variations of distances are reported, although these are rare.

The posterior mandibular angle space is created by an incision made 1 cm anterior to the molars in the gingival buccal sulcus and extending it laterally 4 cm. A sturdy 1 cm layer of mucosa and muscle must be preserved to ensure a secure closure. The dissection is then immediately directed onto the bone. The soft tissues elevate very easily from the inferior border and ascending ramus of the mandible. At the angle itself, there may be tendinous attachments of the masseter muscle, especially in men. These may need lysis with an electrocautery needle to enable the muscles to be disinserted from the angle and posterior border of the mandible. It is critical, however, to disinsert the fibrous attachments at the angle and the posterior border completely so that the implant will seat correctly. The masseter muscle itself is quite thick and strong and will hold it in proper position without fixation. Malpositions and extrusions are rare when the posterolateral space is dissected properly.

A long, curved clamp is placed on the implant to facilitate the posterior and upwards placement of the implant.

A peripiriform premaxillary implant is inserted through a single 4 to 5 mm nasal floor incision, although one on each side may be used if necessary. An intraoral incision in the superior labial sulcus should be avoided, because it may predispose to implant erosion through that area. The plane of dissection is developed deep to the orbicularis oris muscle to create a subperiosteal pocket for the implant.

Tear trough implants can be placed through an external subciliary blepharoplasty incision, a transconjunctival incision, or an intraoral route. The most important consideration is to carefully dissect around the infraorbital nerve under direct visualization to prevent nerve trauma and subsequent disabling symptoms. The tear trough implant is placed after cutting out a segment that allows it to surround the main trunk of the infraorbital nerve. If desired, it can be secured by one or two stitches to the medial orbicularis muscles or to the inferior orbital rim.

Postoperative Care

Postoperative care for facial implants is straightforward and uncomplicated. Oral antibiotics are used perioperatively; at present cephalosporins are favored. Before the procedure begins, the anesthesiologist administers cephazolin (Ancef) 1 g intravenously; 10 mg of dexamethasone (Decadron) is also administered intravenously during the surgery to control postoperative edema. During the postoperative period, a 5-day diminishing course of a steroid (methylprednisone; Medrol Dose-Pak) is taken orally. For the first 12 hours cold compresses are applied intermittently to the operative site either in the midface or premandibular region. No bandages are used. Removal of intraoral mucosal and external subcuticular sutures is unnecessary. A soft diet is maintained for 10 days. It is highly recommended that the patient recline at a 45-degree angle, supine, for at least 1 week. Vigorous physical activity is not permitted for 4 weeks, after which patients may engage in any and all types of exercise.

Problems and Complications

Cellulitis and inflammation developed in this 38-year-old woman after she underwent malar augmentation surgery. *Left and center:* She is seen 10 days after surgery. *Right:* At 3 weeks after surgery, the cellulitis has resolved after treatment with antibiotics and drainage.

Percutaneous suction drainage can be combined with intensive antibiotic therapy to manage a midface suppurative infection.

Extrusion of a central mandibular chin implant is rare but can be caused by excessive trauma or internal pressures created by an inadequate space for the implant.

Intraoral extrusion of a midface implant can follow inferior placement of the implant with overlying pressure erosion caused by a dental prosthesis, hematoma and infection, or inadequate midface anatomic dissection.

A three-dimensional CT scan was used to diagnose the extrusion of this anatomic extended chin implant from the lower internal buccal sulcus mucosa.

The chin implant in this 48-year-old man was adjusted through the previous submental incision and the internal extrusion site was repaired to achieve a successful resolution.

A hematoma that developed during the first 24 hours after surgery caused pain and swelling in this 61-year-old woman. With the patient under local anesthesia, the clots were easily evacuated and the cavity irrigated copiously with antibiotic solution (1 g Ancef in 1 L of Ringer's lactate solution) after the implant was removed. It was immediately replaced and resutured, to heal uneventfully.

This 35-year-old patient sustained damage to the upper lip segment of the orbicularis oris muscle as a result of implant surgery. After 8 weeks, the injury had fully resolved.

Facial nerve injuries are rare following facial implant surgery and are usually temporary. These are examples of temporary damage to the frontalis and orbicularis branches of the left facial nerve after malar augmentation.

Avoiding Unfavorable Results and Complications

In 1991 and 1998, I conducted a survey of ASPRS and ASAPS members regarding their experiences in aesthetic surgery with alloplastic implants. In 2008, a similar survey was done with ASFPS and ASOMS surgeons. The most statistically significant categories for “unfavorable results” with facial implantation reported in all these surveys over the last 20 years were as follows:

1. Patient or doctor dissatisfaction
2. Lack of correction of asymmetries or asymmetries resulting from surgery
3. Inappropriate shape and/or malposition
4. Hematoma, seroma, and inflammation
5. Infection necessitating removal
6. Nerve dysfunction

Notably, in the 1998 survey more than 90% of the surgeons considered their “unfavorable results” to be relatively insignificant, both emotionally and physically. Perhaps this is because the majority of untoward sequelae were either temporary asymmetries and inappropriate shapes associated with the healing phase, reversible problems requiring implant removal, or nerve dysfunctions that in the vast majority were temporary and partial rather than permanent.

More than half of the responding surgeons in the 2008 survey had practices with over 80% cosmetic cases and approximately 10% reconstructive cases. Ninety percent of the surgeons surveyed use alloplastic materials. Silicone rubber implants scored 3 to 1 over the next contender, Medpor. Gore-Tex was used by 25% of the surgeons.

Further evaluation revealed silicone rubber to be the most desirable, as cited by two thirds of the surgeons, Medpor by 20%, and Gore-Tex by 16%. Nearly half of the surgeons stated that silicone (Silastic) was the only material that they used. It was cited for its low infectability; easy insertion, removal, or exchangeability; conformation to the bony skeleton; and stable, long-term, predictable volume. Two thirds of the reporting surgeons use silicone implants for the cheek-midface submalar region and 80% for the chin-mandibular facial aesthetic segment.

For chin implants, twice as many surgeons rated silicone rubber as exceptional or excellent by twice than those who rated the material as fair, good, or useful. In the malar region, Silastic implants were rated six times more successful in achieving exceptional or excellent results than those producing fair, good, or useful results. No one rated facial implants as poor.

Ninety percent of the surgeons surveyed rated facial implant surgeries as useful from 10% to 50% of the time, and 45% of the surgeons felt they would use them in 20% to 50% of cases. Forty percent of the surgeons considered facial volumization with alloplastic materials indispensable or mostly necessary; 60% rated them as desirable or useful at times. Only 0.5% considered them to have too many problems to be used. Although these numbers come from the latest 2008 survey, there has been a significantly increasing endorsement of facial implant technology since my first survey in 1999.

Concluding Thoughts

Clearly, the use of alloplastic facial augmentation has gained tremendous momentum in respectability and success over the past 20 years and apparently is considered one of the leading tools for a plastic surgeon's aesthetic armamentarium for faces.

Clinical Caveats

Always perform the anatomic space dissection directly on the bone and beneath the periosteum.

Maintain the dissecting elevator on the bone at all times.

Never push the tip of an elevator into adjacent soft tissues. This can create severe trauma to the facial nerve, infraorbital nerve and/or zygomaticus muscles disturbing facial expression in the malar-midface region. In the perioral and mandibular regions traumatic dissection into the soft tissues can produce mental nerve or marginal mandibular nerve damage, and even mimetic muscle dysfunction. Potential dangers in posterior angle dissections involve trauma to a large retromandibular vein behind the posterior border of the mandible or to the anterior facial artery just adjacent to the inferior border of the mandible. Disruption of these would produce profuse hemorrhaging.

External palpation of the lower mandibular border with the index finger facilitates an accurate and controlled dissection beneath the mental nerve as well as protecting the inferior soft tissues and marginal branch of the seventh nerve.

Manual palpation externally over the malar region facilitates a precise dissection of the malar space beneath the external preoperative ink markings on the midface skin. A small hockey stick incision with 1.5 cm limbs will facilitate a wide midfacial premaxillary and submalar dissection. Once again, the entry point should be beneath the muscles and onto the bone of the anterior maxillary buttress.

Continued

Clinical Caveats—cont'd

The intraoral chin space dissection should be done vertically between the mentalis muscle pillars to go beneath the muscle and onto the bone without transecting or damaging the mentalis muscle which can produce central chin ptosis.

All intraoral incisions should have a secure muscle and mucosal closure to prevent entrance of bacteria or wound dehiscence.

Intermittent irrigations with copious amounts of antibiotic solution should be performed inside the anatomic zonal spaces during the surgery.

A “no-touch” technique should be meticulously enforced when inserting implants. This is done by placing a clamp on the implant and immersing it in a Betadine and antibiotic solution before inserting it gently into the soft tissue anatomic space aperture.

Implants should be inserted as gently and atraumatically as possible. Finger manipulations are to be avoided. Silicone rubber implants have the advantage of being extremely flexible and therefore easily insertable or removable.

Annotated Bibliography

Binder WJ. Custom-designed facial implants. *Facial Plast Surg Clin North Am* 16:133-146, 2008.

The author presents a comprehensive, detailed, and up-to-date description of this subject, including references to the earliest articles first utilizing these techniques.

Hinderer UT. Malar Implants for improvement of the facial appearance. *Plast Reconstr Surg* 56:157-165, 1975.

This report is one of the earliest to cite the aesthetic value of alloplastic malar augmentation.

Pitanguy I. Augmentation mentoplasty. *Plast Reconstr Surg* 42:460-464, 1968.

This study is one of the earliest to report the value of using chin implants in conjunction with rhinoplasty to accomplish dramatic profileplasty changes.

Ramirez OM. The subperiosteal rhytidectomy: the third-generation face-lift. *Ann Plast Surg* 28:218-232, 1992.

The author describes the use of techniques from craniofacial surgery to achieve extensive subperiosteal elevation of midfacial soft tissues so that they may assume a more elevated position with internal suspension sutures.

Terino EO. Alloplastic facial contouring. In Goldwyn RM, Cohen MN, eds. *The Unfavorable Result in Plastic Surgery—Avoidance and Treatment*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.

This chapter discusses prevention and treatment of all significant facial implant complications. It also reviews results of two major surveys of members of the American Society of Plastic and Reconstructive Surgery in 1991 and members of the American Society for Aesthetic Plastic Surgery in 1998.

Terino EO. Alloplastic facial contouring: surgery of the fourth plane. *Aesthetic Plast Surg* 16:195-212, 1992.

Techniques based on the concepts of zonal anatomy are used to describe alloplastic implants. These implants significantly improve facial contours to correct inherited deficiencies and changes resulting from aging.

Terino EO. Unique mandibular implants including lateral and posterior angle implants. *Facial Plast Surg Clin North Am* 2:311-328, 1994.

This early report emphasizes the versatility of alloplastic premandibular augmentation in achieving a variety of jawline-chin shapes, using several types of implants in the anatomic zones.

Terino EO, Edwards MC. The magic of mid-face three-dimensional contour alterations combining alloplastic and soft tissue suspension technologies. *Clin Plast Surg* 35:419-450; discussion 417, 2008.

The authors present a brief history of facial aesthetic surgery, with references to the source articles.

CHAPTER 40

Applied Anatomy of the Face and Neck

FOAD NAHAI, JUAN DIEGO MEJIA,
FARZAD R. NAHAI

The first rule of anatomy is variation.

Precision in aesthetic surgery depends not only on the technical skills of the operator, but almost equally on the surgeon's detailed knowledge of anatomy. This is particularly pertinent in dealing with aesthetic surgery of the face. A thorough knowledge of the anatomic layers and structures of the face and neck is a prerequisite for successful and safe aesthetic surgery. This includes a comprehensive understanding of the anatomy in three dimensions. The relationship of the underlying bony skeleton, muscles, and subcutaneous tissues, including fascial layers and fat compartments, not only enhances our comprehension of the aging process but is also a key to successful rejuvenation. Anatomic structures and relationships are not consistent, and the surgeon must be aware of possible variations. The anatomy may vary from individual to individual as well as from one side to the other in the same person. Prior surgical interventions may also alter the anatomy and should be taken into account in all secondary aesthetic procedures of the face and neck as well as of the body.

Subcutaneous Fat Compartments of the Face

For many years the subcutaneous fat of the face was believed to be a confluent mass. However, recent anatomic studies by Rohrich and Pessa have demonstrated that this fat exists in distinct anatomic compartments, as shown. These fat compartments are separated by fascial septa that arise from the superficial fascia and insert into the dermis.

Perforating vessels arising from deep arteries travel through these septa to supply the skin and define the overlying vascular territories or angiosomes.

Anatomic Features

Forehead and Temporal Fat Compartments

The forehead is composed of three fat compartments: the central, middle temporal, and lateral temporal–cheek compartments. The central compartment is located in the midline region of the forehead. It is bounded by the middle temporal fat on either side. Its inferior border is the nasal dorsum. This central fat compartment is limited on each side by the central temporal septum. Perforators from the supratrochlear vessels travel through this septum, which explains why the subcutaneous boundaries of the central temporal septum coincide with the known clinical limits of the forehead flap. The middle temporal compartments lie on either side of the central forehead fat. Its inferior border is the orbicularis retaining ligament. Laterally, it is limited by the superior temporal septum and the lateral temporal–cheek compartment. The lateral temporal–cheek fat is the lateralmost compartment of the face. It spans from the forehead to the cervical region, connecting the temporal fat to the lateral cheek and cervical subcutaneous fat.

Orbital Fat Compartments

There are three periorbital fat compartments: the superior, inferior, and lateral orbital compartments. The superior fat is bounded by the orbicularis retaining ligament as it courses around the superior orbit. Medially and laterally, it is limited by the canthi. The inferior orbital fat lies immediately below the inferior lid tarsus. Inferiorly, it is bounded by the orbicularis retaining ligament. The medial and lateral extents are also the canthi. The lateral orbital fat is located in the temporal region. Its superior border is the inferior temporal septum, which carries perforators from the zygomaticoorbital branch. Inferiorly, its boundary is the superior cheek septum. The zygomatic major muscle adheres to this compartment.

Nasolabial Fat Compartment

The nasolabial fat is the medialmost of the facial compartments. The orbicularis retaining ligament represents its superior border. Laterally, it is bordered by the medial cheek compartment, and inferiorly by the nasolabial fat. The lower border of the zygomaticus major muscle is adherent to this fat structure. Perforator vessels from the angular artery run within the nasolabial septum located between the nasolabial fat and the upper lip fat.

Superficial Cheek Fat Compartments

There are three distinct superficial cheek fat compartments: the medial, middle, and lateral temporal–cheek fat.

Medial cheek fat is lateral to the nasolabial compartment. This limit is defined by a septum carrying perforators from the facial and infraorbital arteries. Its superior boundary is the orbicularis retaining ligament and the lateral orbital compartment. The lateral boundary is the middle cheek septum and the middle cheek fat. The jowl lies inferior to this compartment. The facial vein is consistently found at the deep surface of the medial cheek fat.

The middle cheek fat lies between the medial and lateral temporal–cheek compartments. The middle cheek septum is the medial boundary of this compartment; it carries perforators of the transverse facial artery to the skin. This fat compartment is found anterior and superficial to the parotid gland. The zone where the medial cheek fat meets the middle cheek fat corresponds to the location of the parotidomasseteric ligaments. Its superior border is defined by the superior cheek septum. The confluence of septa where this compartment meets the medial cheek fat and the inferior orbital fat forms the zygomaticus ligament. The middle cheek fat is adherent to the zygomaticus major muscle at its superior portion. Care must be exercised during a face lift, because the plane between the lateral and middle cheek compartments can easily lead into the buccal fat pad and deep neurovascular structures.

The lateral temporal–cheek fat is the most lateral compartment of the face. In the cheek, this fat lies immediately superficial to the parotid gland. It spans from the forehead to the cervical region, connecting the temporal fat to the cervical subcutaneous fat. The lateral cheek septum is located anterior to this compartment and corresponds to the first transition zone encountered during a face lift. Multiple perforator vessels from the superficial temporal artery travel through this septum up to the forehead region. The superior and inferior temporal septa represent its superior boundaries.

Deep Medial Cheek Fat Compartment

The deep medial cheek fat is deep to the medial and middle superficial cheek compartments of the face. It lies inferior to the orbicularis oculi muscle and has the orbicularis retaining ligament as its superior boundary. The inferior boundary is the suborbicularis oris fat. The most lateral boundary is the capsule of the buccal fat pad and the zygomaticus major muscle. The medial boundary is the pyriform ligament surrounding the nasal base. The posterior border is the periosteum of the maxilla and a potential space exists between the periosteum and the deep medial fat (Ristow's space), which is a potential site for fat transfer.

Functional Significance

It is unlikely that the face ages as a confluent mass. A smooth transition between subcutaneous fat compartments is characteristic of a youthful face. With aging, somewhat abrupt contour changes between these regions occur. Both volume and position affect the superficial and deep fat compartments in the aging face. These changes may occur as a combination of ligament laxity and volume loss as described by Lambros.

When performing a face lift, the surgeon encounters zones of adherence that alternate with zones of easy dissection, which suggests that barriers exist between different zones of facial fat. These areas occur in the transition between compartments. Transition zones between compartments are regions of potential injury to deeper structures, including branches of the facial nerve. This can occur when transition is performed in too deep a plane during a face lift.

There is a concept that deep cheek fat supports the overlying subcutaneous fat. Loss of volume of the deep medial cheek fat may be a primary determinant of midfacial aging and diminished midface projection. In the aging face, the downward migration of the nasolabial fat as a result of ligament laxity is not the only cause of the observed changes in this area. It seems that the volume of the nasolabial fat is preserved, whereas there is loss of projection of the medial and middle superficial fat compartments of the cheek secondary to deep medial fat atrophy. These findings suggest that one of the reasons for a prominent nasolabial fold with aging is, in part, a

form of pseudoptosis: loss of projection of the superficial medial and middle cheek fat makes the nasolabial fat appear more prominent, when in fact, its volume has not changed. Clinically, when fat is injected into the deep medial fat compartment (deep and medial to the zygomaticus major muscle), this improves midface projection, re-creates a youthful cheek, diminishes the prominence of the nasolabial fold, and improves the lid-cheek junction.

The volume of the nasolabial fat compartment is preserved with age (*black arrow*); however, there is loss of projection of the superficial cheek fat compartments (*red arrow*). A prominent nasolabial fold with age is, in part, a form of pseudoptosis: loss of projection of the superficial cheek fat makes the nasolabial fold appear more prominent.

Muscles of the Scalp and Brow

The muscles of the scalp, brow, and periorbital region are major contributors to facial animation and appearance. Emotional expressions and overall facial appearance depend on the actions of these muscles. With age and repeated contractions, these muscles produce lines or rhytids reflecting the insertion of the muscles into the overlying skin. These characteristic changes result in the familiar patterns of expression and aging on the face. The muscles of the scalp and brow include the epicranii, procerus, corrugator supercilii, and orbicularis oculi muscles. These muscles are responsible for movements of the scalp, forehead, and eyebrows and the rhytids that mark the forehead, glabella, and periorbital areas.

Epicranius

Anatomic Features

The epicranium or scalp muscle is made up of the occipitofrontalis, the major portion, and a variably developed temporoparietalis. The occipitofrontalis is a wide, fibromuscular layer that covers the entire scalp from the nuchal line to the eyebrows. It comprises two paired muscle bellies—the occipital bellies (occipitalis muscles) and the frontal bellies (frontalis muscles); these are connected by the galea aponeurotica. The frontal bellies or frontalis muscles, which are clinically significant, are thin, rectangular muscles without any bony attachments. These muscles are connected posteriorly to the galea aponeurotica at or in front of the coronal suture; they insert anteriorly into the glabellar musculature, where the medial fibers of the frontal belly intermingle with the procerus, while the intermediate fibers mingle with the corrugator supercilii and the orbicularis oculi. The medial fibers of the frontal bellies may be joined together for a variable distance above the root of the nose. Supratrochlear and supraorbital branches of the ophthalmic artery supply the frontalis; it is innervated by multiple branches of the frontal branch of the facial nerve.

Functional Significance

The frontal bellies, acting from above, elevate the eyebrows and forehead. Acting from below, they pull the scalp forward. The frontal bellies are responsible for the transverse forehead wrinkles, reflecting attachments or insertions of the muscle into the overlying forehead skin. Although transverse forehead wrinkles are produced by either action of the frontal bellies, increased tone in the brow depressors, corrugator, procerus, and orbicularis leads to an increase in frontalis tone. This muscle imbalance and increase in tone deepens the forehead lines. The occipital bellies draw the scalp backward, acting in opposition to the downward action of the frontalis. Improvement in brow position after a forehead lift may be attributable to reduced tone in the frontalis following modification of the brow depressors, allowing unopposed action of the occipitalis to elevate the brow. This relationship is the basis of the “functional brow lift” in which no brow fixation is performed.

Galea Aponeurotica

Anatomic Features

The galea aponeurotica is an integral part of the occipitofrontalis and epicranium muscles. It is a thick, fibrous layer with sagittally running fibers between the occipital and frontal bellies. Posteriorly between the separate bellies of the occipitalis, the galea is attached to the external protuberance and highest nuchal line of the occipital bone. Anteriorly it splits to enclose the frontal bellies and continues as a narrowing triangular portion between the two frontal bellies as they converge at the root of the nose. Laterally on each side, coronally running fibers encompass the temporoparietalis and the external ear muscles. The galea is firmly attached to the overlying skin by the firm superficial fascia, which continues as the temporoparietal fascia, eventually attaching to the zygoma. On its deep surface the galea is connected to the epicranium by loose connective tissue and allows movement of the galea and scalp. In the forehead above the level of the supraorbital ridge, there are no nerves or vessels deep to or within this loose connective tissue. This allows rapid, safe brow elevation in the subgaleal or subperiosteal plane. However, the endoscope is essential to visualize the area between the supraorbital rim and supraorbital ridge, where the supraorbital nerve may emerge through a foramen.

The temporoparietalis is a very thin sheet of muscle lying between the frontal bellies of the occipitofrontalis and the auricular muscles. It is variably developed and may be absent.

Procerus

Anatomic Features

The procerus is a small, thin, pyramid-shaped muscle extending from the nasal dorsum to the central forehead. It is considered one of the nasal muscles and may be as large as 2 by 8 cm. It takes origin from the fascia overlying the distal portion of the

nasal bones and upper lateral nasal cartilage and inserts into the skin of the lower forehead between the eyebrows, intermingling with the medial fibers of the frontalis. Branches of the facial artery supply the procerus. It is innervated by the upper buccal branches of the facial nerve.

Functional Significance

The function of the procerus is to pull downward on the medial eyebrows. This action augments the glabellar prominence, producing transverse glabellar wrinkles that are improved with procerus muscle excision.

Corrugator Supercilii

Anatomic Features

The corrugator supercilii is a long, narrow muscle measuring approximately 1 by 5 cm, wider at its origin, narrowing toward its insertion. It lies deep to the frontalis and orbicularis oculi at the medial end of the eyebrow. Originating from the medial end of the supraciliary arch, it has transverse and oblique heads, with fibers running laterally and slightly upward toward their insertion into the central part of the hair-bearing brow. It is supplied by the supratrochlear and supraorbital vessels. Although classically it has been thought that the muscle is innervated by the frontal branch of the facial nerve, Boyd showed that there is additional innervation of the muscle medially through the buccal branches of the facial nerve.

Functional Significance

The corrugator supercilii pulls the eyebrows medially and downward, producing vertical glabellar wrinkles. The depth of these frown lines is related to the thickness of the muscles, their constant contractions, and the thickness of the overlying skin. The transverse head may at times act as an elevator of the medial brow.

Orbicularis Oculi

Anatomic Features

The orbicularis oculi, the most superficial muscle, is a relatively large, flat, broad, elliptical muscle that not only occupies the upper and lower lids and covers the orbit but also extends beyond the orbit onto the cheek and temporal regions. Its fibers form an uninterrupted ellipse. It comprises the orbital, palpebral, and lacrimal portions. The orbital portion is thicker and darker in color than the palpebral portion. Many of its fibers insert into the skin and subcutaneous tissues of the eyebrow and constitute the depressor supercilii. It takes origin from the nasal portion of the frontal bone and the frontal process of the maxilla. The fibers of insertion intermingle with the frontalis and corrugator muscles, inserting into the skin and subcutaneous tissues of the eyebrow. The palpebral portion is thinner and lies within the eyelids. The lacrimal portion of the muscle lies behind the lacrimal sac. The transverse facial, supratrochlear, and supraorbital vessels supply this muscle. The orbicularis is innervated by the temporal, zygomatic, and buccal branches of the facial nerve.

Functional Significance

The orbicularis oculi is a powerful sphincter of the eyelids. It is innervated by the temporal and zygomatic and buccal branches of the facial nerve. The palpebral portion can act involuntarily to close the eyelid, or reflexively, as in blinking. The orbital portion is under voluntary control, and when the entire muscle contracts, in addition to closing the eyelids, the skin of the forehead, cheek, and temple are all drawn toward the medial and lateral canthus, resulting in crow's-feet and eyelid wrinkles. The medial fibers of the orbital portion, known as the depressor supercilii, will depress the medial eyebrow.

The orbicularis oculi is responsible for eyelid movement, both the sphincteric contracture of protective squeezing and normal blinking movements. Historically, the orbicularis has been classified anatomically as having a pretarsal, preseptal, and orbital division. Clinical surgical experience in patients who undergo deconstruction of the eyelids with myoneurectomy to relieve blepharospasm has shown that there is a division of labor between the extracanthal orbicularis and the inner canthal orbicularis.

The extracanthal portion of the orbicularis (*left*) is responsible for squeezing and animation of the eyelid fissure, while the inner canthal portion of the orbicularis (*center*) is responsible for normal blinking, eyelid tone, and tear-pump movement. A division of labor in any muscle group implies a division of innervation, and it has been shown by both clinical experience and EMG studies to be true of the orbicularis muscle.

The extracanthal orbicularis (*right*) is animated primarily by the zygomatic branches of the facial nerve, and the inner canthal orbicularis is innervated by vertical extension of the buccal branch of the facial nerve.

The inner canthal orbicularis muscle segment is much thicker than the extracanthal, has multiple heads, and functions well as the sole motor for eyelid blinking, tone, and tear-pump movement. A counterpull at the lateral canthus to the inner canthal orbicularis contracture is necessary for the proper biomechanics of eyelid closure.

Dissections of branches of the facial nerve in the lower lid canthal area have verified this pattern of innervation. Other studies have shown vertical branches of the zygomatic nerve that run perpendicularly into the pretarsal area, and these researchers have raised concerns of possible denervation of the lower lid with surgical incisions in that area. Recent EMG studies have shown that traditional subciliary incisions and muscle flap dissections in this area produce no denervation.

Other studies have shown that even if the zygomatic branches in the lower lid are removed by tumor resection, that lower lid reinnervation occurs rapidly and the lower lid quickly regains normal function. Intentional denervation of the zygomatic branches to the extracanthal orbicularis in the lower lid in patients undergoing myoneurectomy produces no alteration in blinking, tone, or lid position in these patients.

The muscles of the forehead, brow, and eyelids control brow position. Their actions may also influence facial appearance, creating a tired, angry, or surprised look in some individuals. Chronic contraction or muscle hypertrophy with associated muscle imbalance can cause the development of characteristic transverse forehead wrinkles, vertical and transverse glabellar frown lines, and medial eyelid folds and lateral crow's-feet. Repositioning and selective muscle resection can reverse these aging changes.

The frontalis, procerus, corrugator supercilii, and orbicularis are all intermingled in the medial brow. The degree of development or muscle bulk will vary from individual to individual, depending on habits such as squinting and frowning, which lead to muscle hypertrophy. The procerus, frontalis, and orbicularis are all on the same plane. The corrugator is in a deeper plane at its origin, but laterally it intermingles with the frontalis and orbicularis. As they exit the orbit, the supratrochlear and supra-orbital nerves are intimately involved with these muscles. The supratrochlear nerve is intermingled with the procerus as well as with the medialmost fibers of the corrugator. During resection of the procerus and medial corrugator fibers, the supratrochlear nerve must be identified and preserved. The nerve may not be immediately visible, and muscle separation or partial resection may be necessary for exposure. The supraorbital nerve is intermingled with the more lateral fibers of the corrugator supercilii. If it exits the orbit through a foramen, it is rarely involved with the muscles and is readily identified. However, if it exits through a notch, it is often surrounded by fibers of the corrugator, which may be separated or resected to clearly identify the nerve.

Brow position and dynamics are a function of the balance between the upward and lateral pull of the frontalis and the downward and medial pull of the procerus, corrugator, and orbicularis. Resection of the procerus, corrugator, and orbicularis muscles will alter this dynamic balance and allow the frontalis to elevate the brow with relatively less opposition. This is the underlying hypothesis of medial brow elevation after endoscopic forehead procedures. The lateral fibers of the orbicularis will pull the lateral brow downward; therefore resection of the lateral orbicularis fibers should facilitate lateral brow elevation.

The frontalis and corrugator supercilii are innervated by the frontal branch, the procerus by the upper buccal branches, and the orbicularis by the zygomatic and buccal branches of the facial nerve. Therefore, if the frontal branch is injured or paralyzed, some forehead movement is preserved, especially brow depression around the root of the nose.

This young woman, in undergoing a meningioma resection, had an injury to the frontal branch of the facial nerve on her right side; the asymmetry of the brow position is evident (*left*). With forceful contraction to produce a frown (*right*), the left corrugator produces a vertical line; the right corrugator is paralyzed and the medial brow remains smooth. However, the procerus, innervated by buccal branches of the facial nerve, contracts forcefully, producing typical transverse wrinkling.

Muscles of the Face

The position, tone, and function of the muscles of the face are important for conveying facial expression; an understanding of the anatomy of these muscles, especially their innervation, is essential to avoid injury during aesthetic surgery. The mimetic muscles move the skin of the midface and lips and control the size and shape of the mouth. Freilinger et al described them in four layers. The superficial layer includes the depressor anguli oris, the zygomaticus minor, and the orbicularis oculi. The next layer includes the depressor labii inferioris, the risorius, the platysma, the zygomaticus major, and the levator labii superioris alaeque nasi. The next layer includes the orbicularis oris and the levator labii superioris. The deepest layer includes the mentalis, the levator anguli oris, and the buccinator.

The muscles of the first three layers are innervated by the facial nerve on their deep surface, but the muscles in the fourth layer are innervated by the facial nerve on their superficial surface. The superficial musculoaponeurotic system (SMAS) and the muscles of the upper three layers that it invests can be thought of as a unit controlling facial skin movement, similar to the arrangement of muscles and fascia controlling scalp and forehead movements.

Muscles of the Mouth

The shape and size of the mouth and the position of the lips are controlled by an extensive collection of small muscles: a group of muscles that elevates and retracts the upper lip, a group that depresses and retracts the lower lip, and a sphincter that controls the size and shape of the mouth. Elevators and retractors of the upper lip include the levator labii superioris alaeque nasi, levator labii superioris, zygomaticus major, zygomaticus minor, levator anguli oris, and risorius. Depressors and retractors of the lower lip are the depressor labii inferioris, depressor anguli oris, and mentalis. The sphincter function is controlled by the buccinator and orbicularis oris (see the illustrations on p. 1286).

Levator Labii Superioris Alaeque Nasi

Anatomic Features

The levator labii superioris alaeque nasi is a long, narrow muscle that takes origin from the upper part of the frontal process of the maxilla. The fibers pass obliquely downward and laterally along the nasofacial line superficial to the levator labii superioris. This muscle has two slips of insertion: the medial slip inserts into the lower lateral cartilage of the nose and the lateral slip inserts into the lateral part of the upper lip, blending with the levator labii superioris and orbicularis oris fibers. It is innervated by the buccal branches of the facial nerve and receives its blood supply from the facial artery.

Functional Significance

The medial insertion slip dilates the nostril and the lateral insertion slip elevates and everts the upper lip.

Levator Labii Superioris

Anatomic Features

The levator labii superioris is a narrow, triangular muscle lying deep to the levator labii superioris alaeque nasi that takes origin from the zygoma and maxilla along the inferior orbital rim just above the infraorbital foramen. The fibers course medially from this orbital origin toward the lip where they insert into the muscular substance of the upper lip between the lateral slip of the levator labii superioris alaeque nasi and the levator anguli oris. The blood supply is through the transverse facial artery, and the muscle is innervated by the buccal branch of the facial nerve.

Functional Significance

The levator labii superioris elevates and everts the upper lip, and, along with the zygomaticus minor, it forms the nasolabial sulcus.

The zygomaticus major and zygomaticus minor muscles are important considerations during dissection deep to the mobile SMAS, as in deep plane and composite face lifts. These muscles lie superficially just below the malar fat pad and the dissection of the deep plane lift is just above them. The lower margin of the orbicularis oculi is also beneath the malar fat pad but superficial to these two muscles.

Zygomaticus Major

Anatomic Features

The zygomaticus major is a relatively long, thin (1 by 7 cm) muscle that originates from the zygoma behind and above the origin of the zygomaticus minor. The fibers course medially toward their insertion in the lip. It is supplied by the transverse facial artery and innervated by buccal branches of the seventh nerve that enter its deep surface.

Functional Significance

The zygomaticus major draws the angle of the mouth upward as well as laterally.

Zygomaticus Minor

Anatomic Features

The zygomaticus minor is also a long, thin (1 by 4 cm) superficial muscle that originates on the lateral surface of the zygoma just behind the zygomaticomaxillary suture. The fibers also insert into the muscular substance of the upper lip. It lies superficial to the levator labii superioris and is supplied by the transverse facial artery and innervated by the buccal branches of the facial nerve.

Functional Significance

The zygomaticus minor elevates the upper lip and forms the nasolabial sulcus with the levator labii superioris.

Levator Anguli Oris

Anatomic Features

The levator anguli oris, a small quadrangular muscle, lies deep to the zygomaticus minor and levator labii superioris. It originates on the maxilla just below the orbital foramen and inserts into the muscle substance of the lip.

Functional Significance

The levator anguli oris raises the angle of the mouth and deepens the nasolabial fold. The infraorbital neurovascular bundles lie between the levator anguli oris and the levator labii superioris.

Depressor Labii Inferioris

Anatomic Features

The depressor labii inferioris is continuous with the platysma at its origin from the oblique line of the mandible between the mental foramen and the symphysis. Its fibers run upward and medially, inserting into the lip.

Functional Significance

The depressor labii inferioris draws the lip downward and laterally.

Depressor Anguli Oris

Anatomic Features

The depressor anguli oris pulls the angle of the mouth downward and is continuous with the platysma at its origin from the oblique line of the mandible below and lateral to the origin of the depressor labii inferioris. The platysma produces similar actions in the lower lip.

Mentalis

Anatomic Features

The mentalis is a very thick, small muscle that originates from the incisor foramen of the mandible and inserts into the chin.

Functional Significance

The mentalis raises and protrudes the lower lip, creating chin wrinkles.

Buccinator

Anatomic Features

The buccinator is a relatively large, thin, deep muscle that lies in the cheek in the interval between the maxilla and mandible. It is innervated by the buccal branches of the facial nerve.

Functional Significance

The buccinator compresses the cheek against the teeth. The name *buccinator* (trumpeter) reflects its function of expelling air between the lips, as in blowing. Superficial to the buccinator posteriorly, the buccal fat pad separates it from the mandibular ramus, masseter, and temporalis. The parotid duct pierces the muscle opposite the upper third molar, and this muscle is spread when the buccal fat pad is removed through an intraoral incision. The facial artery and buccal branches of the facial nerve cross the muscle.

Orbicularis Oris

Anatomic Features

The orbicularis oris is a very superficial muscle constituting the bulk of the lips and acts as an oral sphincter. The majority of the muscles of facial expression insert into this muscle, which is made up of several layers of muscle fibers all running in different directions. The fibers from nine muscles converge at the oral commissure, forming the modiolus. The zygomaticus major, levator anguli oris, and depressor anguli oris can fix the modiolus in any given position, thus influencing the position of the oral commissure.

Functional Significance of the Mimetic Muscles

The muscles of facial expression are innervated by the seventh nerve, and their function must be preserved during aesthetic facial surgery. The fascial layers of the face have a constant position relative to the nerves and muscles; precise facial dissection technique and knowledge of the location of these muscles and nerves will minimize the risk of postoperative muscle weakness and asymmetry.

The mimetic muscles control facial expression (such as smiling and grimacing), the position and shape of the mouth, and even to a certain extent the position of the eyelid and eye shape. The effect of these muscles on the nasolabial fold is not clearly established. The nasolabial fold deepens when the face is animated, as in smiling, and the nasolabial fold disappears with facial paralysis. Rubin et al showed that the nasolabial fold is composed of subcutaneous fat, muscle fibers of the lip elevators, and striated muscle fibers originating from the fascia. The authors hypothesized that the fold becomes more prominent with age as a result of loss of subcutaneous fat. Pessa and Brown showed that resection of the levator labii alaeque nasi and partial resection of the levator labii superioris muscle decrease the medial nasolabial fold and soften the acute nasolabial angle seen with aging. Experience with *botulinum* toxin injections has confirmed these findings. These authors further studied the effect of individual mimetic muscles on the nasolabial fold in cadavers. They identified the levator labii alaeque nasi as the primary facial muscle responsible for creating the medial nasolabial fold. They demonstrated that the levator labii superioris defined the middle nasolabial fold and the zygomaticus major had a slight effect, deepening the lateral portion of the nasolabial fold. Hypothetically, subperiosteal face lifts in which the origins of several of these mimetic muscles are rearranged may alter the depth and prominence of the nasolabial fold.

Muscles of the Neck

Platysma

Anatomic Features

The platysma is key to the changes in the neck attributed to aging, and modification of this muscle not only is necessary to improve the appearance of the aging neck, but also has a dramatic effect on neck reshaping. With aging, the platysma descends and tends to become redundant centrally in the submental region. This is manifest by vertical platysmal bands that are first seen with animation but later become permanently visible. The amount of subcutaneous tissue overlying and attached to the platysma, especially in the jowl and submental region, can also cause descent of the platysma, which contributes to submental fullness and flattening of the cervicomental angle.

The platysma is a large, broad, thin sheet of muscle spanning the neck from the mandible to below the clavicle. It originates from the fascia overlying the pectoralis and deltoid muscles. The fibers cross the clavicle and course upward and medially. The anterior fibers interlace and mingle with fibers from the opposite side below the symphysis of the mandible, inserting into it and laterally along the border of the mandible into which they also insert. Posteriorly, fibers cross the lower border of the mandible and insert into the SMAS. The dominant pedicle is a branch of the submental artery, and the minor pedicle is a branch of the suprasternal artery. It is innervated by the cervical branch of the facial nerve.

Functional Significance

Within the submental area the anatomy of the muscle varies greatly from individual to individual. Cardoso de Castro's anatomic studies led him to classify the relationship of the two platysma muscles and their interdigitations or decussation in the submental area into three types:

- Type I Most common: occurs in 75% of cases; demonstrates a limited decussation of the platysma muscles extending 1 to 2 cm below the mandibular symphysis
- Type II Occurs in 15% of cases; demonstrates decussation of the platysma from the mandibular symphysis to the thyroid cartilage
- Type III Occurs in 10% of cases; demonstrates no decussation or interdigitations

This confirms our clinical impression that in the majority of patients there is very limited interdigitation of the muscles medially, as evidenced by the two visible platysma bands in an aging neck.

Functionally, the platysma draws down the lower lip and the angle of the mouth and diminishes the neck-jaw angle. The platysma may vary in size and extent. Asymmetry of the platysma is not uncommon, and rarely, the platysma may be absent on one side. In a thin neck, tightness and youthful contour of the facial-mandibular line as

well as the submental and anterior neck regions are influenced by the tone of the platysma. When the tone is normal, these angles are sharp and well defined; when the tone is poor, the angles may become blurred and indistinct. Baker and colleagues stated that retaining ligaments within the neck support the platysma and tightly maintain it in position against the deep cervical fascia, creating the acute cervicomental angle characteristic of youth. These fibers or ligaments are present along the posterior mandibular border throughout the subplatysmal fat and extend between the platysma and hyoid and upper aspect of the thyroid cartilage. Thus, as this platysmal support weakens with age, the anterior free edge of the muscle no longer firmly adheres to the deep cervical fascia and droops, forming platysmal bands. Loss of skin elasticity is also a contributing factor. With these changes, the acute cervicomental angle is gradually lost and assumes an oblique direction. Excess fat may accumulate superficial to the platysma in the jowl, in the submental region, and centrally in the subplatysmal region. Hypertrophy of the anterior belly of the digastric muscles may add further fullness to this midline region. The platysma covers the submandibular glands, and with platysmal laxity or glandular hypertrophy, a bulge gradually becomes visible below the jawline laterally, within the submental triangle.

Correction of the aging neck focuses on tightening the platysma centrally and in its upper lateral region by tightening its attached SMAS. Usually the medial platysma is approached through a submental incision, and the skin and subcutaneous tissues are separated from the muscle and the redundant muscle tightened after contouring the fat superficial and deep to the platysma. When the submandibular glands are prominent, the platysma can be tightened over them, although gland resection is more effective.

Muscles of Mastication

Masseter

Anatomic Features

The masseter is a large, quadrilateral muscle originating in three layers that fuse anteriorly. The fibers run downward and backward from the maxillary and zygomatic origins to the mandibular insertion. The superficial layer, the largest portion of the muscle, has a thick aponeurotic origin from the zygomatic process of the maxilla and the lower border

of the anterior two thirds of the zygomatic arch. The middle and deep layers take origin from the deep surface of the zygomatic arch.

The anterior edge of the masseter has a concavity that faces the oral commissure. In the upper part, the anterior border of the masseter angles backward parallel to the nasolabial fold. At the level of the oral commissure, the anterior border of the muscle changes direction and angles forward to insert into the body of the mandible. This anterior curvature of the masseter is associated with an attachment on the body of the mandible that is 25 to 30 mm more anterior than is usually illustrated. This triangular-shaped forward prolongation of the muscle's lower anterior part is the basis for the jowl recess.

Superficial to the masseter lie the SMAS, platysma, risorius, zygomaticus major, parotid gland, and parotid duct. The masseter is lined by the thin but strong masseter fascia. After exiting the parotid gland, branches of the fascial nerve travel beneath this fascia, which acts as a protective layer. The transverse facial artery crosses the muscle. On its deep surface lie the ramus of the mandible, the insertion of the temporalis, and the buccal fat pad that separates it from the buccinator.

Temporalis

Anatomic Features

The temporalis is a large, fan-shaped muscle originating from the entire temporal fossa and the deep temporal fascia. Its fibers converge and descend deep to the zygomatic arch to insert onto the coronoid process of the mandible. The outer border is separated from the zygoma by the deep temporal fat pad. The temporalis muscle is covered by several fascial layers that are important for safe elevation of the forehead and lateral upper face.

Functional Significance

These large muscles of mastication are important landmarks during forehead and subperiosteal face lifts. The origins of the superficial layer of the masseter from the zygomatic process of the maxilla and the lower border of the zygomatic arch are taken down during a subperiosteal face lift. Branches of the facial nerve, transverse facial artery, and parotid duct cross the superficial surface of the masseter muscle.

The buccal fat pad lies between the masseter and buccinator. The temporalis is invested by the deep temporal fascia and separated from the zygoma by the deep temporal fat pad. The temporal crest lines represent the origin of the temporalis.

Facial Bones

Knowledge of the bony anatomy is essential to performing both open and endoscopic techniques for facial rejuvenation. It is especially important for subperiosteal lifts of the forehead and midface.

Detailed knowledge of the shape and contour of the bone, its foramina, the vessels and nerves they emit, and the muscles that take origin and insert into the bone will facilitate endoscopic as well as open dissection and minimize the risk of injury.

Frontal Bone

Anatomic Features

The frontal bone forms the forehead and is connected anterolaterally with the zygoma and centrally with the nasal bones, frontal process of the maxilla, and lacrimal bone. The central portion of the frontal bone is rounded. This frontal tuberosity lies on either side of the midline approximately 3 cm above the orbit. It is variable in size and is usually more pronounced in women and children. This convexity will influence access incisions and endoscopic pathways across the forehead and mandates the use of curved instruments. Below the frontal tuberosity and approximately 1 cm above the orbit there is a pair of curved superciliary arches. These arches are more pronounced in men. The smoother area between the two arches is the glabella. These upper orbital rims are sometimes reduced to give the lateral brow a lighter, more open look. The orbital rims lie below the superciliary arches.

Foramina

The supraorbital notch, or foramen, is located at the junction of the medial third and lateral two thirds of the orbital rim (midpupillary line). This foramen contains the supraorbital nerve and vessels. Approximately 1 cm medial to the supraorbital foramen is the frontal notch or foramen. It is present in only 50% of patients. The supratrochlear vessels and nerves pass through this foramen.

Muscle Origins and Insertions

The temporalis muscle originates from the temporal fossa, which is located primarily on the temporal bone, but anteriorly is made up of the greater wing of the sphenoid and a small portion of the frontal bone. The temporal line or crest originates along the zygomatic process of the frontal bone and extends upward and backward across the frontal and parietal bones. It usually begins as a single line or crest, and as it passes posteriorly, it divides into two. The origin of the temporalis includes this line or crest, and the deep temporal fascia is firmly adherent to this line. The transition from subperiosteal to subgaleal forehead dissection takes place at this line. The corrugator supercilii takes origin from the medial end of the superciliary arch. The orbicularis oculi takes origin from the nasal part of the frontal bone. None of the forehead muscles inserts into bone. They exert their actions directly on the overlying skin.

MUSCLE ORIGINS AND INSERTIONS

Functional Significance

The shape—specifically, the convexity—of the frontal bone will influence the location of incisions and endoscopic access to the forehead. If there is significant curvature of the forehead, the central access incision should be placed closer to the hairline to reduce the arc that the rigid endoscope must traverse. Conversely, if the forehead is relatively flat, the access incision may be placed farther back on the scalp, still affording access to the glabella and orbital rim. The curved forehead instruments are designed to overcome this contour barrier.

Along the supraorbital margin, where the orbital rim is smooth medially, the periosteum appears less adherent. The supraorbital nerve exits the orbit through the supraorbital notch or foramen. If a foramen is present, it is usually located approximately 5 to 10 mm above the orbital rim, but may rarely be as high as 20 mm or so.

The periosteum and deep temporal fascia are firmly adherent to the temporal crest. The transition from subperiosteal to subgaleal forehead dissection takes place at this line, making this an important landmark during endoscopic forehead dissection. This line also represents an important preoperative landmark; if the lateral access incisions are placed lateral to this line, brow fixation can be done by suturing the galea to the superficial layer of the deep temporal fascia. Incisions lateral to the line also protect the lateral branch of the supraorbital nerve. If the incision is medial to the anterior temporal crest line, other methods of fixation may be required, because there will be no strong fascial layer under the access incision. This crest line is readily palpable in most patients. If it is not, forced contraction of the temporalis (clenching of the teeth) will delineate the anteromedial border of the muscle, indicating its origin from the anterior crest line.

Zygomatic Bone

Anatomic Features

The zygomatic bone forms the cheek prominence and contributes to the lateral wall of the orbit and the walls of the temporal and infratemporal fossae. The orbital border (anterosuperior) is smooth and forms part of the orbital rim. The frontal process articulates with the zygomatic process of the frontal bone anteriorly and with the greater wing of the sphenoid posteriorly. On the orbital aspect of the frontal process approximately 1 cm below the frontozygomatic suture line, there may be a tubercle into which the lateral canthal ligament inserts. The temporal process runs posteriorly and articulates with the zygomatic process of the temporal bone.

Foramina

Along the lateral surface of the zygoma near the orbital border, one or perhaps two zygomaticofacial foramina are present. Through this foramen (or foramina) the zygomaticofacial nerve and vessels pass. The zygomaticotemporal foramen, which contains the zygomaticotemporal nerve as it leaves the orbit, is located more superiorly and posteriorly within the temporal fossa.

The masseter has an extensive area of origin from the posteroinferior border of the zygoma. The zygomaticus major originates on the lateral surface of the zygoma just above and behind the origin of the zygomaticus minor, whereas the zygomaticus minor originates on the lateral surface of the zygoma just below and anterior to the origin of the zygomaticus major. The origin of the levator labii superioris is along the lateral portion of the infraorbital rim of the zygoma.

Functional Significance

Deep plane face-lift dissection is above the origin of the zygomaticus major. During subperiosteal face-lift dissection the periosteal attachments to the zygoma are completely freed. This includes portions of the zygomatic origin of the masseter, the origin of the zygomaticus major and minor, and the levator labii superioris. The attachment of the temporoparietal fascia to the zygoma is also divided. Subperiosteal dissection along the zygoma through a temporal, eyelid, or intraoral incision may lead to disruption of the zygomaticofacial nerve, which can be easily identified and preserved. The zygomaticotemporal nerve is not involved in this dissection.

Nasal Bones

Anatomic Features

The nasal bones are small paired, oblong bones that vary in size and shape from individual to individual. A small vascular foramen on the external surface transmits a small vein. The nasal bones are covered by the nasalis and procerus muscles. The procerus muscle takes origin from the nasal bone and upper lateral cartilage. Removal of the procerus requires dissection down onto the nasal bones. With elevation of the forehead, some of the pull can be transferred to the nasal tip.

Maxilla

Anatomic Features

The maxilla is the second largest facial bone; it forms the entire upper jaw and contributes most of the roof of the mouth, lateral wall and floor of the nose, and floor of the orbit. It contains the maxillary sinus. The maxilla comprises a body and four processes: zygomatic, frontal, palatine, and alveolar. The zygomatic process articulates with the zygoma and the frontal process articulates with the frontal bone and nasal bones.

Foramina

Above the canine fossa and approximately 1 cm below the orbital rim is the infra-orbital foramen, which contains the infraorbital nerve and vessels. Above is the origin of the levator labii superioris and below is the origin of the levator anguli oris. The nerve is located between these two muscles as it exits the infraorbital foramen, in the midpupillary line.

The orbicularis oculi originates from the frontal process of the maxilla. The levator labii superioris alaeque nasi originates from the upper part of the frontal process of the maxilla and the levator labii superioris originates immediately above the infra-orbital foramen. The levator anguli oris takes origin from the canine fossa just below the infraorbital foramen and the buccinator from the alveolar process above the three molars.

Aging Changes

At birth the vertical length of the maxilla is much smaller than its horizontal diameters (transverse and anteroposterior). The frontal process is well developed, but the body is little more than the alveolar process with tooth sockets lying just below the orbit. With growth, as the maxillary sinus enlarges and the alveolar processes develop, the vertical height increases significantly. With age, especially after loss of the teeth, vertical height diminishes, and there is a gradual regression toward the neonatal state.

Functional Significance

During subperiosteal face-lift dissection, the infraorbital foramen must be identified and the nerve and vessel preserved. It is easily identified 1 cm below the orbital rim in the midpupillary line. The origin of the mimetic muscles from the maxilla is taken down during subperiosteal face-lift dissection.

Mandible

Anatomic Features

The mandible is the largest and strongest of the facial bones; it has a U-shaped body and two vertical rami extending upward from the posterior part of the body. The external surface of the body is marked in the midline by a line or ridge, the symphysis mend representing the line of fusion of the two halves of the fetal mandible. The symphysis extends inferiorly to the mental protuberance in the midline and the mental tubercles on each side. The mental tubercle and protuberance represent the chin prominence.

Foramina

The mental foramen is located 1 cm below the second premolar or the gap between the first and second premolars. Through this foramen pass the mental nerve and vessels. The midpupillary line is also a good landmark for identification of the nerve.

The buccinator originates from the outer surface of the alveolar process of the mandible opposite the three molars. The mentalis takes origin from the incisive fossa of the mandible. The depressor labii inferioris takes origin from the oblique line of the mandible above the origin of the depressor anguli oris between the symphysis and the foramen. The depressor anguli oris originates from the oblique line of the mandible below the origin of the depressor labii inferioris and below the mental foramen. The temporalis inserts into the coronoid process. The masseter inserts into most of the outer surface of the ramus. The platysma inserts along the outer inferior border of the mandible.

Aging Changes

After all of the permanent teeth have erupted, the mandible undergoes constant change and remodeling. The depth of the body increases, the alveolar portion of the bone grows larger, and the bone becomes thicker and deeper. The mental foramen in the early years is much closer to the upper border of the bone and opens midway between the upper and lower borders of the bone in the adult. With old age, especially when the teeth are lost, the bone is reduced in size. After loss of the teeth, the alveolar portion is absorbed so that the mental foramen is closer to the alveolar border. With age, the angle between the ramus and the body also decreases. At birth this is an obtuse angle, but it eventually reaches a 90-degree angle in adulthood and in old age reverts to a more obtuse angle.

Blood Supply of the Facial Soft Tissues

Arterial Supply

The face and scalp are extremely well vascularized through an extensive network of intercommunicating vessels. These vessels not only communicate with each other but across the midline with corresponding vessels on the opposite side. The facial soft tissue blood supply is abundant, and a clear understanding of the communications between the underlying vessels and the overlying subcutaneous tissues and skin makes it possible to perform aesthetic facial surgery safely with minimal risk of skin necrosis, even in patients who smoke.

The entire blood supply of the face and scalp is based on the carotid system. Almost all of this circulation is based on the external carotid artery and its branches, with a small contribution to the eyelid, brow, forehead, and scalp through the palpebral supratrochlear and supraorbital branches of the ophthalmic division of the internal carotid artery.

In their exhaustive study of the blood supply of the face and scalp, Whetzel and Mathes described 11 vascular territories based on 14 individual arteries. They further subdivided the face into an anterior region supplied by five vessels, a lateral region supplied by four vessels, and a scalp and forehead region supplied by five vessels.

Vascular Territories of the Face and Scalp

Anterior Face	Lateral Face	Scalp and Forehead
Facial	Transverse	Superficial temporal
Superior labial	Submental	Frontal branch of superficial temporal
Inferior labial	Zygomaticoorbital	Temporal branch of superficial temporal
Supratrochlear	Anterior auricular	Posterior auricular
Supraorbital		Occipital

In each of the three major scalp and face regions, the pattern of arterial vascularization is distinct. The anterior face is supplied by a large number of small, densely populated musculocutaneous perforating branches; the lateral face by a small number of large, sparsely populated fasciocutaneous perforators with predictable locations; and the forehead and scalp region by a large number of small, densely populated fasciocutaneous perforators.

External Carotid Artery

The external carotid artery contributes to the facial soft tissue blood supply through its facial, occipital, posterior auricular, superficial temporal, and maxillary branches.

The facial artery takes origin from the front of the carotid artery in the carotid triangle above the lingual artery and just above the greater cornu of the hyoid bone. It runs medial to the ramus of the mandible, arching upward and grooving the posterior surface of the submandibular gland. Between this gland and the medial pterygoid it runs downward to the border of the mandible where the submental artery branches off. The facial artery then hooks around the lower border of the mandible at the anterior edge of the masseter muscle insertion. It is superficially located here just under the platysma and is crossed by the marginal mandibular branch of the facial nerve. It may even groove the mandible as it curves around the mandible and ascends to the angle of the mouth over the buccinator and deep to the mimetic muscles. At the angle of the mouth the superior and inferior labial arteries branch off and the facial artery ascends along the nasofacial line to end in an anastomosis with the dorsal nasal branch of the ophthalmic artery. During this portion of its course it runs deep to or within the levator labii superioris alaeque nasi. Branches of the facial artery contribute to the blood supply of soft tissue and skin of the face and include the submental artery, inferior labial artery, superior labial artery, and lateral nasal vessel. Most of the contribution from the facial artery and its branches to the overlying skin is through densely populated multiple musculocutaneous vessels.

The submental artery takes origin from the facial artery just as it turns upward over the inferior border of the mandible. It runs forward below the body of the mandible lying on the mylohyoid muscle. It supplies the surrounding muscles, then courses over the mandible at the chin where its branches anastomose with branches of the inferior labial and mental arteries to supply the skin of the chin through musculocutaneous perforators. The inferior and superior labial arteries arise at the angle of the mouth. The superior labial artery is the larger of the two vessels. The inferior labial artery runs deep to the depressor anguli oris and then penetrates the orbicularis oris muscle, running a tortuous course just deep to the vermilion border to form an anastomosis with the inferior labial artery from the other side. Similarly, the superior labial artery runs deep to the levator anguli oris and then enters the orbicularis oris, and through musculocutaneous perforators these two vessels supply the skin and mucosa of the lip and chin.

The labial vessels run within the orbicularis oris muscle just deep to the vermilion border, where they may be at risk during injection of filler materials for lip augmentation.

The occipital artery takes origin from the posterior aspect of the external carotid artery opposite the origin of the facial artery and runs posteriorly along the deep border of the posterior belly of the digastric muscle to the posterior scalp. It supplies the posterior scalp and eventually forms an anastomosis with the supratrochlear and supraorbital vessels.

The posterior auricular artery is a small branch that takes origin from the posterior aspect of the external carotid artery just above the digastric and the stylohyoid muscles. It runs upward between the parotid gland and the stylohyoid process of the temporal bone to the groove between the ear cartilage and the mastoid process. It then divides into an auricular branch supplying the cranial skin (medial surface) of the ear and an occipital branch that supplies the retroauricular skin and will eventually form an anastomosis with branches of the occipital artery.

The superficial temporal artery is the smaller of the two terminal branches of the external carotid artery. It takes origin within the parotid gland and courses upward, crossing the zygoma, and approximately 5 cm above the zygoma it divides into its two terminal branches—the frontal and parietal. Within the parotid gland it is crossed by the temporal and zygomatic branches of the facial nerve and in the scalp it is accompanied by the auriculotemporal nerve that lies deep to it. The five branches of the superficial temporal artery that supply the face and scalp are the transverse facial, anterior auricular, zygomatic orbital, and its two terminal branches—the frontal and parietal.

The transverse facial artery takes origin from the superficial temporal artery within the parotid gland and runs forward through the gland. It crosses the masseter below the zygomatic arch and above the parotid duct accompanied by the zygomatic and buccal branches of the facial nerve. It supplies a large area of the lateral midface and has a large number of terminal branches that form an anastomosis with branches of the facial and infraorbital arteries. The transverse facial artery supplies the overlying skin through large fasciocutaneous perforators. The most prominent of these perforators is usually located at the junction of the lateral third and medial two thirds of the line drawn from the auditory canal to the nasal spine.

The zygomaticoorbital artery may sometimes take origin from the middle temporal rather than the superficial temporal artery. It runs along the upper border of the zygomatic arch accompanied by a vein to the lateral orbital rim and within the two layers of the temporal fascia. It supplies the overlying skin through three or four fasciocutaneous perforators, the largest of which is usually located at the junction of the lateral third with the medial two thirds of the line from the auditory canal to the nasion.

The frontal branch of the superficial temporal artery takes origin 5 cm above the zygoma and runs anteromedially. It forms multiple anastomoses with the vessel on the opposite side and with branches of the supraorbital and supratrochlear vessels. It supplies the overlying skin through musculocutaneous perforators. The parietal or posterior branch of the superficial temporal artery is the larger of the two terminal branches. It runs upward and backward, forming multiple anastomoses with the vessel on the opposite side and with the postauricular and occipital arteries.

The internal maxillary artery contributes to the blood supply of the facial soft tissues and skin through the mental and infraorbital branches. The mental artery is the terminal branch of the inferior alveolar artery, which is a branch of the first or mandibular portion of the internal maxillary artery. The small vessel emerges through the mental foramen of the mandible accompanied by the mental nerve. Its branches form an anastomosis with the inferior labial and submental branches of the facial artery. Through musculocutaneous perforators it contributes to the blood supply of the chin and lips.

The infraorbital artery is a branch of the third (pterygopalatine) portion of the maxillary artery. It enters the orbit through the posterior part of the inferior orbital fissure and runs along the infraorbital groove and canal with the infraorbital nerve to emerge onto the face through the infraorbital foramen deep to the levator labii superioris. It descends between the levator labii superior and levator anguli oris. Its branches form an anastomosis with branches of the facial, superior labial, and transverse facial artery to supply the overlying skin through musculocutaneous perforators.

Internal Carotid Artery

The internal carotid artery contributes to the blood supply of the forehead and scalp through the supraorbital and supratrochlear branches of its ophthalmic division and the eyelids through the palpebral branches. The supraorbital artery accompanied by the supraorbital nerve leaves the orbit through the supraorbital foramen or notch and divides into superficial and deep branches. It supplies the overlying muscle and through musculocutaneous perforators the forehead skin. Its terminal branches form an anastomosis with the supratrochlear and frontal branch of the superficial temporal artery. The supratrochlear artery is one of the terminal branches of the ophthalmic artery and leaves the orbit accompanied by the supratrochlear nerve along the superior and medial aspect of the orbit. There may be a definite notch in the orbit where the vessel and nerve exit. This vessel supplies musculocutaneous perforators to the overlying skin and forms an anastomosis with branches of the supraorbital artery.

The small paired palpebral arteries supply the eyelids. The medial palpebral arteries (superior and inferior) take origin directly from the terminal portions of the ophthalmic artery below the trochlear head of the superior oblique muscle. They enter the eyelids and then run along the tarsus to form an anastomosis with the lateral palpebral vessels. The lateral palpebral arteries are branches of the lacrimal artery.

Functional Significance

The facial vessels lie primarily in the deepest plane of the face with the parotid duct and buccal and zygomatic branches of the facial nerve. These vessels are avoided in a subperiosteal face lift as well as in deep plane and composite face lifts. The contribution of the facial vessels to the blood supply of the skin is through a network of musculocutaneous perforators located along the oral commissures and the nasolabial

folds. As noted by Whetzel and Mathes, the anterior region of the face receives its blood supply through a dense network of musculocutaneous perforators, whereas the lateral face is supplied through a network of sparsely populated fasciocutaneous perforators. Skin undermining during rhytidectomy will divide these fasciocutaneous perforators located laterally. The blood supply to the facial flap is then dependent on the medially located musculocutaneous perforators. Further separation of skin from subcutaneous tissue toward the nasolabial fold will divide these perforators. The deep plane approach preserves these musculocutaneous perforators and thus enhances and maintains skin flap circulation.

The forehead blood supply is plentiful, and ischemia of the forehead and scalp is rare even following the transcoronal approach, because the blood supply to the overlying skin is through musculocutaneous perforators, which are not disturbed except with the subcutaneous brow-lift technique. The blood supply to the scalp hairs is plentiful. However, it can be compromised by excess tension or by sutures that strangle the blood supply to incision margins. Since the length of skin incisions is limited and the surrounding subdermal plexus is preserved, endoscopic approaches should help to prevent or limit hair loss.

Injection of filler materials should be performed with caution in the glabellar region and lips. Intraarterial injection, especially under pressure, may lead to vascular compromise and in the periorbital area may lead to visual problems through forceful retrograde flow into the central retinal artery. The safer and preferred method is to push the syringe plunger while withdrawing the needle.

Venous Drainage of the Face and Neck

Although not as critical to the survival of soft tissues and flaps during facial rejuvenation, knowledge of the venous drainage of the head and neck is essential, because some of the veins bear a close anatomic relationship to nerves we strive to protect during facial dissection (for example, the frontal branches of the facial nerve and the sentinel vein, great auricular nerve, and external jugular vein). Intraoperative injury of the veins will lead to profuse bleeding. Although rare, postoperative hematoma may be related to intraoperative venous injury. Knowledge of the venous drainage will contribute to our understanding of postoperative facial swelling.

The following discussion of the venous drainage of the head and neck is not as detailed as that of the arterial supply; only the significant anatomic points and relationships as they affect face and neck dissection are presented. The venous drainage of the head and neck is divided into a superficial and a deep system. Aesthetic surgeons normally encounter only the superficial system.

Facial Vein

Anatomic Features

The supratrochlear and supraorbital veins drain the forehead and anterior scalp. These vessels start in the anterior scalp and forehead and join each other along the medial border of the orbit to form the facial vein. The facial vein then runs along the medial border of the orbit and root of the nose, coursing downward and backward with the facial artery. It passes under the zygomaticus major, descending obliquely toward the mandibular border. Along this part of its course, it is related to the facial artery and the branches of the facial nerve. It crosses the border of the mandible and runs superficial to the submandibular gland, posterior belly of the digastric muscle and courses posteriorly to join the internal jugular vein at the level of the hyoid bone.

Functional Significance

The facial vein has no valves, and through its tributaries, the supraorbital vein and the superior ophthalmic vein, it communicates with the cavernous sinus. The clinical relevance is that any infection involving the facial vein may extend into the intracranial venous system. The facial vein lies deep to the zygomaticus major and should be safe during deep plane dissections over the zygomaticus major muscle.

Superficial Temporal Vein

Anatomic Features

The superficial temporal vein drains the temporal and posterior scalp region and communicates with the supratrochlear and supraorbital veins through tributaries. This vein takes a more superficial route than the facial vein, crossing the zygomatic arch and running across the superficial surface of the parotid gland. It receives numerous tributaries and is eventually joined by the posterior auricular vein to become the external jugular vein. The occipital vein drains the lateral and posterior scalp, piercing the trapezius muscle at the junction of the head and neck to join the deep cervical and vertebral veins, and through its tributaries communicates with the posterior auricular vein.

Functional Significance

On rare occasions, extensive posterior dissection in the retroauricular area may expose the occipital vein.

The posterior auricular vein courses along the retroauricular area and is a communicating vein between the occipital and the external jugular, which is made up of the union of the postauricular and superficial temporal veins. These are all superficial veins and may be injured during facial dissections.

Veins of the Neck

The veins of the neck are divided into superficial and deep, depending on their relationship to the deep fascia of the neck. The superficial veins are tributaries of the external jugular and drain the subcutaneous structures of the neck. The deep veins all drain into the much larger internal jugular vein and are rarely exposed during aesthetic surgery.

External Jugular Vein

The external jugular vein receives most of the blood from the face and scalp. It is made up of the union of the superficial, temporal, and posterior auricular vein. It originates at the level of the mandibular angle and runs down the neck to the middle of the clavicle, entering the subclavian vein just behind the clavicle. The external jugular is covered by the platysma muscle along most of its length, and it lies over the deep cervical fascia. The great auricular nerve ascends along the vein toward the face.

Functional Significance

The external jugular vein is at risk during dissection deep to the platysma and is in close relationship with the great auricular nerve, as the nerve courses upward toward the ear.

Anterior Jugular Veins

Several small veins in the submandibular region join on each side to become the anterior jugular veins, which descend along the mylohyoid muscle and the sternohyoid muscles toward the sternal notch, draining eventually into the external jugular vein or directly into the subclavian. These veins are of variable size.

Functional Significance

The anterior jugular veins are often at risk during subplatysmal dissection and may bleed profusely. They are easily identified, running from above downward along the medial border of the strap muscles.

Sentinel Vein

Anatomic Features

The zygomaticotemporal veins (two of them) are communicating veins between the superficial and deep system. They connect the superficial system through the temporalis to the deep venous system of the face. These paired vessels are located above the zygoma and lateral to the orbital rim. The more lateral of the two is usually smaller in size and is accompanied by the zygomaticotemporal nerve. The larger, more medial vessel is called the sentinel vein. It is a very useful anatomic landmark for identifying clinically, preoperatively and intraoperatively, the course of the frontal branches of the facial nerve. When present, the vein is easily identified during a brow lift, whether by an open or endoscopic approach. The branches of the facial nerve usually course 1 cm above this vein. The name “sentinel vein” may be a misnomer, because by the time the dissection has reached the vein, it has already passed deep to the nerves.

Functional Significance

In most patients the location of the sentinel vein is visible when the patient is in the recumbent position. A centimeter above the vein, a mark is made on the skin indicating the course of the frontal branch of the facial nerve. Brow-lift dissection can proceed rapidly up to that point, then slowly and carefully, under endoscopic or open control, until the sentinel vein has been identified. This is a useful guideline for avoiding possible injury to the frontal branches of the facial nerve that run in or just superficial to the temporoparietal fascia.

Whenever possible, these communicating veins should be preserved. Cauterization or tying off of these veins will lead to further prominence of veins in the periorbital area.

Lymph Nodes of the Face and Neck

Anatomic Features

During face and neck lifts it is not uncommon to encounter superficial lymph nodes. The most commonly encountered lymph nodes are the retroauricular nodes lying behind the ear over the sternomastoid, and the superficial cervical nodes on the superficial surface of the sternomastoid. These lymph nodes may be encountered during the retroauricular and neck dissections. Anteriorly on occasion the superficial parotid nodes may be encountered during sub-SMAS dissection. The submental lymph nodes are encountered during subplatysmal or interplatysmal dissections.

Functional Significance

If lymph nodes are encountered during the dissection for face or neck lifts, they should be evaluated and dealt with appropriately. These lymph nodes are usually small and normal. However, if they have an unusual appearance or are large in size, it would be advisable to do an excisional biopsy. The presence of these lymph nodes or encountering them during the dissection should not affect the conduct of the operation in any way, nor will it affect the final result.

Sensory Nerve Supply

The sensory innervation of the face and scalp is based on the trigeminal nerve and cervical spinal nerves with a small contribution to the auditory canal through the eighth and tenth cranial nerves. Each of the branches of the trigeminal nerve has its own well-delineated skin territory. That of the ophthalmic division is supplied through the supraorbital, supratrochlear, infratrochlear, lacrimal, and external nasal branches; that of the maxillary through the zygomaticotemporal, zygomaticofacial, and infraorbital branches; and the mandibular through its auricular temporal, buccal, and mental branches.

Ophthalmic Division

Anatomic Features

The frontal nerve is the largest branch of the ophthalmic division entering the orbit through the superior orbital fissure above the muscles. It runs forward in the orbit and divides into a small supratrochlear branch and a larger supraorbital branch. The supratrochlear branch runs medially forward above the trochlea of the superior oblique muscle emerging from the orbit medially. It curves upward accompanied by the supratrochlear branch of the ophthalmic artery to innervate the central portion of the forehead. The supraorbital is the larger of the two branches and passes forward to the supraorbital notch or foramen to exit with the supraorbital branch of the ophthalmic artery to innervate the forehead and scalp. The lateral branch of the supraorbital nerve is the major sensory nerve of the scalp and enters the hair-bearing scalp medial to the temporal crest.

The infratrochlear nerve is a small branch of the nasociliary nerve that runs along the medial wall of the orbit near the pulley of the superior oblique muscle. It receives a branch from the supratrochlear nerve and leaves the orbit to supply the medial eyelid and a small area on the upper medial side of the nose. The lacrimal nerve, the smallest branch of the ophthalmic artery, innervates the lacrimal gland and leaves the orbit to innervate the eyelids and a small area of the adjacent temporal region.

Functional Significance

The supraorbital and supratrochlear nerves are important considerations when performing a brow lift. These nerves course in a paramedial position upward in the forehead to the scalp and dividing them causes hypesthesia of the dome of the scalp. There is slow return of sensibility after division of these nerves, and patients often experience paresthesia, pruritus, and other annoying side effects. The supraorbital nerves are usually spared during an endoscopic forehead lift. With midline and lateral temporal incisions, the main branches of these nerves are left undisturbed. The endoscopic forehead approach benefits from the magnification by permitting the surgeon to remove the corrugator and procerus muscles while sparing the branches of the supraorbital and supratrochlear nerves.

The supraorbital nerve is much larger than the supratrochlear nerve. It leaves the orbit through a definite notch or occasionally through a foramen located approximately 1 cm above the orbital rim. Whereas the supraorbital nerve is usually a single thick nerve, the supratrochlear nerve may have several branches rather than a thick trunk. The supraorbital nerve can be marked on the skin at the supraorbital rim above the midpupillary line. This corresponds well with the skin markings for the infraorbital nerve located 1 cm below the infraorbital rim in the midpupillary line. This same midpupillary line, continued below the lip, marks the location of the mental nerve. The lateral branch of the supraorbital nerve represents the main sensory innervation of the scalp and runs along the temporal crest or medial to it. Incisions in the scalp crossing medially past the temporal crest risk injury to the nerve and scalp numbness.

The supratrochlear nerve lies within or deep to the medial fibers of the corrugator muscle, and its medial branches may be associated with the fibers of the procerus. The supraorbital nerve is also associated with the lateral fibers of the corrugator. During subperiosteal endoscopic or open myectomy, part of each muscle must usually be removed to fully expose these nerves. When these nerves lie deep to the muscle, they are seen before muscle dissection, because the subperiosteal endoscopic approach allows visualization of these structures from their deep surface.

Maxillary Division

Anatomic Features

The maxillary division innervates the skin of the midface through its zygomaticotemporal, zygomaticofacial, and infraorbital branches. The zygomatic nerve arises in the pterygopalatine fossa and enters the orbit through the inferior orbital fissure. It courses along the lateral border of the orbit and divides into two branches, the zygomaticotemporal and zygomaticofacial nerves.

The zygomaticotemporal nerve passes along the inferior wall of the orbit and exits through a foramen into the temporal fossa and ascends between the bone and the temporalis, piercing the deep temporal fascia 2 cm above the zygomatic arch to innervate the skin of the temple region. Along the terminal part of its course it is accompanied by one of the zygomaticotemporal veins, the lateral one. The zygomaticofacial branch passes along the inferolateral border of the orbit and exits through a foramen in the zygomatic bone and then through the orbicularis oculi to innervate the skin of the cheek below the zygoma. The maxillary nerve is a purely sensory nerve when it enters the orbit through the inferior orbital fissure and becomes the infraorbital nerve. It runs along the infraorbital groove to exit through the infraorbital foramen accompanied by the infraorbital branch of the internal maxillary artery. It innervates the skin of the cheek and upper lip.

Functional Significance

The skin marking for the infraorbital nerve is in the midpupillary line 1 cm below the infraorbital rim. The zygomaticotemporal nerve pierces the deep temporal fascia 2 cm above the zygoma and 2 cm lateral to the orbit. It is easily identified and just as readily injured during open or endoscopic subgaleal dissection in the lateral brow–temporal region. Division of the nerve leads to some minor sensory loss in the temporal region. The zygomaticofacial nerve exiting through a foramen in the zygoma just lateral to the orbit is located directly in the path of subperiosteal dissection. This nerve is easily identified and preserved. Division of the nerve will result in a small area of sensory loss below the zygoma. The zygomaticotemporal nerve is often identified during endoscopic brow lifts, accompanied by the more lateral of the two zygomaticotemporal veins.

Mandibular Division

Anatomic Features

The mandibular nerve innervates facial skin through the auriculotemporal, buccal, and mental branches. The auriculotemporal nerve arises from two roots encircling the middle meningeal artery. It runs backward under the lateral pterygoid muscle on the surface of the tensor veli palatini to pass between the sphenomandibular ligament and the neck of the mandible. The buccal branch of the mandibular nerve passes forward between the two heads of the lateral pterygoid muscle and then deep to or through the lower part of the temporalis muscle to emerge from under the mandibular ramus and anterior border of the masseter. It communicates with buccal branches of the facial nerve and then innervates the skin of the cheek over the buccinator. The mental nerve, the continuation of the alveolar nerve, exits the mandible through the mental foramen to innervate the chin and lower lip.

Functional Significance

The auriculotemporal nerve courses with the superficial temporal artery and is easily and quite often injured or divided during open face-lift and brow-lift procedures. The mental nerve exits through the mental foramen at the level of the second premolar and the skin markings are 2 cm below the lip in the midpupillary line, making it easily identified and preserved during open or endoscopic exposure for alloplastic implant placement.

Nerves of the Cervical Spine

Anatomic Features

The cervical spinal nerves innervate the neck, ear, lower face, and posterior scalp. The greater occipital nerve is the medial branch of the dorsal ramus of C2. It ascends obliquely between the inferior oblique and semispinalis capitis, which it pierces. It then pierces the trapezius and runs upward and forward to innervate the scalp up to the vertex. The superficial ascending branches of the cervical plexus are branches of the ventral rami; the lesser occipital C2, greater auricular C2-3, and transverse cu-

taneous C2-3 innervate the lower lateral face, upper neck, submental area, and most of the ear. The lesser occipital nerve arising from C2-3 curves around the accessory nerve ascending along the posterior border of the sternocleidomastoid and continues upward on the side of the skull behind the ear. It innervates a small portion of the medial surface of the ear and the posterolateral neck and scalp.

The greater auricular nerve is the largest of the ascending branches of the cervical plexus. It arises from the dorsal rami of C2-3, encircles the posterior border of the sternocleidomastoid muscle, perforates the deep fascia 6.5 cm below the external auditory canal, and then courses upward. At this point it may lie deep to the platysma and is accompanied by the jugular vein. However, during its upward course toward the parotid gland, it lies within the subcutaneous tissues. At the level of the parotid it divides into anterior and posterior branches. The anterior branch innervates the skin of the face over the parotid and the posterior branch and continues upward to innervate the skin over the mastoid process and most of the medial and lateral surfaces of the ear, including the concha and lobule.

The transverse cutaneous nerve of the neck arises from the dorsal rami of C2-3 and turns around the posterior border of the sternocleidomastoid muscle at about its midpoint. It then runs obliquely forward and upward deep to the platysma and external jugular vein toward the anterior border of the sternocleidomastoid muscle where it divides into an ascending and a descending branch. The ascending branch innervates the submandibular and submental regions, and the descending branch innervates the side and front of the neck.

Functional Significance

The great auricular nerve is the most commonly injured nerve during open rhytidectomy. It is at greatest risk in its superficial location on the sternocleidomastoid muscle, 6.5 cm below the external auditory canal. Division of the nerve will lead to numbness of portions of the ear. Although this numbness is a nuisance, the possibility of a neuroma developing in the cut end of the nerve poses even greater problems. These nerves can be blocked as they exit the posterior surface of the midsternocleidomastoid muscle.

Motor Nerve Supply

Facial Nerves

Anatomic Features

Surgeons performing facial aesthetic surgery must have a clear understanding of the facial nerve. Damage to a single branch of this nerve causes a visible muscle palsy and significant facial asymmetry, distressing to both patient and surgeon. Fortunately, most postoperative facial muscle weakness is caused by reversible stretch injuries to the facial nerve branches; however, division of the nerve, although rare, is always a possibility.

The facial nerve emerges through the stylomastoid foramen and is immediately protected by the parotid gland. Within the parotid gland it divides into an upper and lower portion and then into its five major branches: the temporal (frontal), zygomatic, buccal, marginal mandibular, and cervical. The branches then emerge medially from the parotid gland lying initially on the superficial surface of the masseter and deep to the parotideomasseteric fascia (deep facial fascia). Beyond the masseter muscle, the branches lie over the buccal fat pad, and at this level the facial nerve branches, the parotid duct, and the facial vessels are all at the same depth. Facial nerve branches proceed medially and innervate the mimetic muscles on their deep surface, except for the deepest level muscles, the mentalis, levator anguli oris, and

buccinator, which are innervated on their superficial surfaces. Dissection during deep plane or composite face-lift procedures, either endoscopic or open, superficial to the zygomaticus muscles will also be superficial to the facial nerve branches.

Although the facial nerve branches are deep and well protected during facial dissection, the frontal branches and marginal mandibular branch are most at risk. The frontal branches, unlike the others that lie deep to the facial fascial layers, assume a superficial course once they cross the zygomatic arch. They cross the zygomatic arch at approximately the midpoint of a line drawn from the tragus to the lateral canthus. At this level they assume a superficial course running within the sub-SMAS fat just deep to the temporoparietal fascia. More distally they pierce the temporoparietal fascia to innervate the frontalis on its deep surface.

Along the medial portion of its course, the marginal mandibular branch is well protected by the parotid gland. Beyond the parotid it is protected by the rather thick SMAS platysma layer. Here it usually runs at or below the mandibular margin. As it crosses the facial vessels deep to the platysma it courses upward and is usually located well above the mandibular margin. At the level of the facial vessel, the platysma and fascia are usually thinner.

The marginal mandibular branch in its peripheral course follows the mandibular border. Before crossing the facial vessels it may extend 1 or 2 cm below the border of the mandible. However, once it has crossed the facial vessels, it always runs above the border of the mandible. It is deep to the platysma throughout its course; however, as the platysma thins, this nerve could be in jeopardy. To prevent injury to the nerve, any subplatysmal dissection should begin at least 2 cm below the angle of the mandible. Dissection above the platysma laterally and deep to the platysma centrally will avoid nerve injury.

Functional Significance

Injuries to the buccal and zygomatic branches of the facial nerve are extremely rare. These branches of the facial nerve are located deep to the SMAS and the deep facial fascia. For injury to occur during rhytidectomy not only must the SMAS layer be penetrated but also the deep facial fascia. Since there are multiple interconnections between the buccal and zygomatic branches, injury to one or more branches would probably not result in a clinically noticeable deficit.

Dissection deep to the fixed or immobile portion of the SMAS (the portion adherent to and overlying the parotid gland) is safe and best performed sharply with a scalpel or scissors, but dissection deep to the mobile SMAS, beyond the parotid gland, must be done cautiously and should be performed bluntly by spreading rather than cutting.

The frontal and marginal mandibular branches are at greater risk. The frontal branch assumes a superficial course after it crosses the zygomatic arch. In this area a violation of the SMAS or superficial fascial layer (temporoparietal fascia) may result in nerve injury. Lower on the cheek, however, the SMAS and deep facial fascia must be penetrated before the buccal or zygomatic branches are placed at risk. Therefore a safe plane of dissection in the temporal region would be either deep or superficial to the frontal branch. When combining an open coronal brow lift with a face lift, the dissection above the zygoma is in the loose areolar plane deep to the temporoparietal fascia on top of the superficial layer of the deep temporal fascia and below the temporoparietal fascia. Below the zygoma the dissection is in the more superficial subcutaneous level, leaving an intervening “mesentery” to protect the nerve.

During an endoscopic brow lift, injury to the frontal branch can be avoided in several ways. Lateral dissection in the plane immediately above the superficial layer of the deep temporal fascia in the lateral brow must proceed cautiously in a medial to in-

ferolateral direction. The location of the nerve should be anticipated from its anatomic course, and the surgeon should be aware of the sentinel vein, which indicates proximity to the nerve. Elevation in this plane using a sweeping motion with smooth rounded elevators allows identification of this vessel. Alternative routes of dissection involve flap elevation in a deeper plane, either below the superficial or deep layers of the deep temporal fascia. Either location further separates the plane of dissection from the nerve. Undue upward force during these deep dissections (including subperiosteal elevation of the zygomatic arch) may cause trauma to the nerve and should be avoided.

During an open or endoscopic subperiosteal face lift, the superficial layer of the deep temporal fascia is incised and dissection proceeds deep to this layer within the superficial temporal fat pad to the zygoma. This keeps the dissection well below the course of the frontal branch.

Facial Danger Zones

Facial danger zones have been described by Seckel where motor branches and sensory nerves are at greatest risk during facial rejuvenation. These include the frontal, zygomatic, buccal, and marginal mandibular branches of the facial nerve, the great auricular nerve, supraorbital, infraorbital, and mental nerves.

Fascial Layers, Adhesions, and Ligaments of the Face

Knowledge of the fascial layers, adhesions, and ligaments of the face contributes to surgeons' understanding of the changes resulting from the aging process and enables us to precisely prepare surgical procedures, not only within the appropriate layer of the face, but also in planning the release of adhesions and ligaments to mobilize the tissues and easily reposition them. Adequate mobilization and repositioning of facial tissues depends on complete release of the adhesions and ligaments before mobilization. An understanding of the layers of the face clarifies the anatomic relationships and defines the planes of dissection for mobilization of tissues in facial rejuvenation.

If the facial soft tissues are conceptualized as a series of concentric layers, as proposed by Stuzin, Baker, and Gordon, the aesthetic surgeon will understand that dissection within one anatomic plane can proceed without disturbing the other layers. From superficial to deep, these layers include skin, subcutaneous tissue, superficial facial fascia (SMAS), premasseter space, mimetic muscles, and deep facial fascia (parotidomasseteric fascia); the deepest plane contains the facial nerve, parotid duct, buccal fat pad, and facial vessels. These layers and various structures, although

anatomically distinct, function as one unit to convey facial expression. Changes within each layer and the effects that these changes have on the other layers produce the visible signs of facial aging.

Subcutaneous Layer

The thickness of the subcutaneous layer varies not only from individual to individual but within different areas of the same face. There is scant, if any, subcutaneous fat overlying the zygoma; it is most plentiful over the cheek, jowl, and submental areas. Fullness and descent in these areas causes cheek flattening, accentuation of nasolabial folds, jowl formation, and fullness of the central neck.

Superficial Facial Fascia, Superficial Musculoaponeurotic System *Anatomic Features*

The SMAS is considered to be a well-defined portion of the superficial facial fascia. This superficial facial fascia is a discrete fascial layer forming a continuous sheath through the face and neck and extending into the malar region, the lip, and even the nose. It extends into the forehead, temporal area, and scalp as the temporoparietal fascia. This layer separates the subcutaneous tissues from the underlying muscles and the deep facial fascia and facial nerves.

The SMAS represents an upward extension of the superficial cervical fascia into the face, and the temporoparietal fascia can be considered an extension of the SMAS into the temporal and scalp regions. This layer varies in thickness. It is very thick over the parotid gland (SMAS), the temporal region (temporoparietal fascia), and the scalp (galea); it is much thinner over the masseter muscle and becomes thinnest in the malar region. Just like the subcutaneous fatty tissues, it will vary in thickness from individual to individual.

The attachment of the SMAS throughout the face is not uniform. It has areas of tight adherence to the underlying structures in some areas, whereas in others it separates with less difficulty making a SMAS elevation possible even with blunt dissection.

In surgical terms, we often divide the SMAS into the fixed and mobile portions. The fixed portion lies over the parotid gland; it is firmly adherent to the gland and is immobile. The mobile portion, beyond the parotid gland, lies directly over the mimetic muscles, facial nerves, and parotid duct. It is not adherent to the structures and is highly mobile. It is mobilization and traction on this part that results in movement of the midface and lower face.

Functional Significance

The muscles of facial expression, the mimetic muscles, are bound by the superficial fascial layer and arranged in four layers, as described by Freilinger et al. The muscles most likely to be visualized during rhytidectomy—the orbicularis oculi, platysma, and zygomaticus major and minor—are all superficially located and all innervated by the facial nerve on the deep surface.

Only the deepest muscles—the buccinator, mentalis, and levator anguli oris—lie deep to the plane of the facial nerve and are innervated on their superior surface. Clinically, this is significant in that SMAS elevation can be performed safely as long as the plane of dissection stays above these muscles. In deep plane rhytidectomy, dissection along the anterior surface of the zygomaticus major muscle can be performed safely, since this dissection is superficial to the nerve branches and the muscle is innervated on its deep surface.

It is only through mobilization and traction on the mobile SMAS that the facial tissues can be effectively mobilized, elevated and repositioned.

Premasseter Space

Anatomic Features

The soft tissues overlying the masseter can be divided into two separate areas. An oblique line that goes from the inferior edge of the tragus to just below the oral commissure separates the upper masseteric area from the lower masseteric area. The upper area contains the zygomatic branch of the facial nerve, the accessory lobe of the parotid and parotid duct, and the upper buccal trunk of the facial nerve.

The lower area contains what is referred to as the *premasseter space*. This is an avascular cleavage plane that contains no facial nerves, where the SMAS is easily elevated. This space underlies the SMAS and platysma and is superficial to the masseter fascia. It is a true space with a rhomboid shape and defined boundaries where the SMAS separates with less difficulty, making a safe SMAS elevation possible even with blunt dissection.

The floor of the premasseter space is made up of the masseter fascia. No facial nerve branches are at risk while dissecting through this space as the branches course beneath the fascia of the masseter. The roof of the premasseter space is formed by the superficial fascia that encloses the upper aspect of the platysma. This fascia is strongly adherent to the platysma fibers. The platysma continues up from the neck in an oblique fashion over the premasseter space. At the anterosuperior border of the space, the platysma has a strong deep fixation to a key masseteric cutaneous ligament. There are no facial nerve branches within the roof of the premasseter space.

The superior border of the premasseter space is limited by a strong septum that is tightly bound by a posterior ligament and an anterior key masseteric cutaneous ligament. The location of this septum is represented by a line that crosses the surface of the masseter from the inferior edge of the tragus to the oral commissure. This is the line that bisects the masseter into an upper and a lower area. The lower area (premasseter space) is the safe area where sub-SMAS dissection can be performed with ease.

The posterior border of the pre-masseter space starts 25 to 30 mm anterior to the tragus and extends down to about 15 mm above the angle of the mandible. The area between the ear and the posterior border of the space is lined by immobile SMAS that is tightly adherent to the underlying structures, particularly the parotid capsule. The posterior border of the pre-masseter space (25 to 30 mm anterior to the tragus, just anterior to the edge of the parotid) represents the end of these dense attachments, and the beginning of the mobile SMAS. When a sub-SMAS dissection is planned, it should be started 25 to 30 mm anterior to the tragus where the pre-masseter space begins. The presence of a defined space under the SMAS makes this dissection easier and safer. When in the space, further dissection of the SMAS should be blunt and atraumatic which further reduces the chances of nerve injury. There is no advantage in performing this dissection in the tightly adherent immobile SMAS. An additional benefit that comes from not dissecting the immobile SMAS is that a segment of firm adherent tissue remains to anchor the newly surgically repositioned mobile SMAS.

The inferior border of the space is made up of a thin membrane that extends from the previously described posterior border, approximately 15 mm superior to the angle of the mandible, all the way to the mandibular ligament at the labiomandibular crease. The upper mandibular branch of the facial nerve crosses the posterior border of the masseter approximately 8 mm above the angle of the mandible then continues below the inferior border of the pre-masseter space. This makes the inferior

border of the premaseter space cephalad to the mandibular branch, which remains outside the operative field at all times. Clinically, there is no advantage to be gained in extending the sub-SMAS dissection to the rim of the mandible. Except for the mandibular ligament anteriorly, there are no ligamentous fixations along the inferior septum. This makes the inferior boundary of the space more predisposed to inferior displacement when there is descent of the tissues with age.

The anterior border of the premaseter space is defined by the anterior border of the muscle. The forward prolongation of the muscle's lower anterior part for 20 to 25 mm is the basis for the jowl recess at the anteroinferior corner of the premaseter space. Medial to the anterior membrane is a sheet of masseteric ligaments that provide structural support and form a "picket fence"-like reinforcement of the border. This ligamentous support extends from the key masseteric cutaneous ligament at the anterosuperior border of the space down to the mandibular ligament. The mandibular ligament is located immediately in front the jowl recess and it demarcates the transition between the jowl and the labiomandibular fold. The more the jowl descends, the more apparent this demarcation becomes.

Anterior to the premaseter space, on the medial side of the ligaments, course several branches of the facial nerve that came from beneath the floor of the space. Further medial to the premaseter space, between the masseteric ligaments and the oral commissure, is the masticator space which contains the buccal fat pad. In youth, the inferior border of the masticator space is at the oral commissure, separate from the jowl recess. With significant aging changes and ligament laxity, this space, along with the buccal fat, can extend down so low as to contribute to the heaviness of the jowls and labiomandibular folds. Adequate rejuvenation of the jowls and labiomental folds may sometimes require management of the buccal fat pad. Surgical access to the buccal fat can be obtained through the attenuated anterior border of the premaseter space.

Functional Significance

The jowl and labiomandibular fold are classical signs of aging. Correction of the jowls and labiomandibular folds are two of the most essential elements for a successful face-lift. The SMAS and the jowls seem to be closely related since the manipulation of the SMAS during a face lift achieves improvement of the jowl. The pre-masseter space is implicated in the formation of jowls. With aging, a progressive attenuation of the masseteric ligaments causes laxity of the anterior and inferior border allowing the roof to slide down. The changes along the anterior border are not uniform. There is less laxity above where there is a stronger fixation by the thick key masseteric ligaments, and there is more laxity below in the jowl recess. With ligament laxity, there is descent of tissues into the anteroinferior area of the pre-masseter space extending below the mandible rim, resulting in the development of the jowl. Improvement in the laxity of the jowls and labiomandibular folds can be obtained

through a posterosuperior pull of the mobile roof (SMAS) of the premassester space. Sub-SMAS dissection through this avascular space is easy and safe since it contains no vital structures. The amount of pull possible increases in older patients because of the laxity of the masseteric cutaneous ligaments. If a SMASectomy is required, it becomes an effective and safe technique since a strip of SMAS is being resected from the roof of the space without any risk of nerve damage. The nearest facial nerve branches (buccal) are under the floor of the space.

Deep Facial Fascia

Parotideomasseteric Fascia

The superficial layer of the deep cervical fascia continues onto the face as the deep facial fascia. In the area overlying the parotid it is referred to as the investing fascia of the parotid and over the masseter it is called the masseteric fascia. The deep facial fascial layer extends to the malar region lying deep to the lip elevators, and its extension above the zygomatic arch is the deep temporal fascia. The clinical significance of this layer is that the facial nerve branches within the cheek all lie deep to it. The superficial fascia and deep facial fascia are separated by loose areolar tissue typical of the usual arrangement between fascial layers elsewhere in the body. However, these two layers are firmly attached to each other in certain anatomic locations. In the temporal region there is an areolar plane between the temporoparietal (superficial facial fascia) and the deep temporal fascia (deep facial fascia). In the areolar tissue between them lie the temporal artery and the frontal branch of the facial nerve. A similar plane is found in the cheek between the SMAS (superficial facial fascia) and the parotideomasseteric fascia (deep facial fascia) over the masseter muscle and between the platysma and the strap muscles in the neck. The two facial fascial layers are firmly attached to each other along the zygomatic arch over the parotid gland and along the anterior border of the masseter.

The Deepest Plane

The deepest plane lying deep to the deep facial fascia or parotideomasseteric fascia contains the zygomatic and buccal branches of the facial nerve, the buccal pad, the parotid duct, and the facial artery and vein.

Functional Significance

The clinical significance of these four facial layers involves their relationship to the branches of the facial nerve and their preservation during rhytidectomy. Any dissection superficial to the SMAS is obviously well away from the underlying nerves. Below the SMAS and above the deep facial fascia, dissection within the cheek will protect the buccal and zygomatic branches. However, the frontal branch requires special attention once it crosses the zygoma and assumes a superficial course. Since the zygomaticus muscles are innervated on their deep surface, deep plane rhytidectomy superficial to the zygomaticus muscles does not place the facial nerve branches at risk.

Path of dissection

Continued path of dissection

Variation

Retaining Ligaments and Adhesions of the Face and Neck

Temple and Periorbital Region

Temporal Ligamentous Adhesions

Proper elevation and rejuvenation of the periorbital area, specifically the lateral brow and lower lid-cheek junction depends on appropriate release of a variety of adhesions and ligamentous attachments. There are numerous adhesions and attachments in this area. They have been given different names and described as different types of structures by various authors. Some of the adhesions and ligaments in this area have been referred to as tendons, though no real tendons in the anatomic sense are present in the region.

The medial and lateral third of the eyebrow above the orbit is held in position by the temporal ligamentous adhesions. These extend posteriorly along the temporal crest as the superior temporal septum or the temporal line of fusion. These adhesions extend medially toward the medial orbit as the supraorbital ligamentous adhesions. Laterally from the supraorbital rim the adhesion extends toward the posterior and upper border of the zygoma in the form of the inferior temporal septum. More anteriorly, directly over the orbital rim—starting medially and extending counterclockwise around the orbit—are the periorbital septum superiorly, extending laterally to the lateral brow thickening of the periorbital septum, farther down laterally along the orbital rim to the lateral orbital thickening of the periorbital septum, and then around the lower lateral portion of the orbit and along its inferior border as the lower extent or continuation of the periorbital septum. As described by Moss, Mendelson, and Taylor, essentially the periorbital septum extends around the orbit from the upper medial area of the orbit to the lower medial portion covering three quarters of the circumference of the orbit.

Periorbital Ligaments

Functional Significance

Complete division of these adhesions and septa is essential for repositioning of the lateral brow and periorbital tissues. These adhesions are usually very easily dissected with a periosteal elevator. However, sometimes the lateral brow thickening of the periorbital septum may require division using the scissors rather than a periosteal elevator.

Remembering and recounting the names of these various adhesions and attachments is not as important as remembering that it is essential to divide all of them to allow adequate mobilization of the lateral brow and periorbital tissues.

Midlateral Face

Anatomic Features

Retaining ligaments of the midlateral face run from underlying fixed bony origins into the overlying dermis. The ligaments serve to support the facial skin in its normal anatomic position. Based on their anatomic studies, Stuzin and colleagues described two types of retaining ligaments. The first, or true osseocutaneous ligaments, run from the periosteum to the dermis (for example, the zygomatic and mandibular ligaments). The second system is formed by the coalescence of the superficial facial fascia and the deep facial fascia that fixes the facial layers to underlying structures such as the parotid and masseter and are attached to the overlying dermis by fibrous septa. The parotid cutaneous and masseteric cutaneous ligaments are examples of this second system. These much finer structures also serve to maintain facial soft tissue in its normal position. The zygomatic ligaments take origin from the body of the zygoma and the zygomatic arch and extend through the malar fat pad to the overlying dermis. The mandibular ligaments originate in the parasymphyseal region of the mandible and extend to the overlying dermis. Masseteric cutaneous ligaments are located along the entire anterior border of the masseter, where the superficial facial fascia and deep facial fascia are firmly adherent. A series of fibrous bands extends vertically up to the dermis to support the cheek skin. The parotidocutaneous ligaments lie along the parotid gland, where the superficial facial fascia and the deep facial fascia are firmly adherent to each other and similar septa anchor the overlying skin down to the fascia.

Functional Significance

These ligaments are essentially fixed structures extending from underlying bone to dermis. Facial tissue, especially fat pads, can pivot around them, producing creases such as the marionette grooves of the lower face. With age, these ligaments attenuate and relax. This, combined with the loss of skin elasticity and soft tissues, will lead to the stigmata of aging. The zygomatic ligaments suspend the malar soft tissues and fat pad over the zygomatic prominence. As this support weakens, the malar soft tissues gradually migrate downward, and redundant skin hangs over the fixed nasolabial sulcus. Rather than the nasolabial sulcus deepening with age, it is the downward migration of the soft tissues against the fixed nasolabial sulcus that accounts for the observed changes. Surgical correction of the prominent nasolabial fold should concentrate on repositioning the malar soft tissues and restoring malar support. In a similar fashion, attenuation and weakness of the masseteric cutaneous ligaments will allow a downward shift of the cheek tissues below the mandibular margin, where tethering by the mandibular ligament will lead to the formation of jowls. Surgical correction of jowls should include a rearrangement and resuspension of the deep tissues. These ligaments that extend from bone to dermis must be released during a face lift to achieve the desired result. Left intact, they limit mobility.

Malar and Buccal Fat Pads

Malar Fat Pad

Anatomic Features

A youthful appearance with the associated cheek prominence is related to the prominence of the underlying zygoma as well as the position and fullness of the malar fat pad. Owsley noted that the malar fat pad is an area of increased thickening of the subcutaneous tissues extending from the malar region to the nasolabial crease. This fat pad is located superficial to the SMAS and mimetic muscles. It is roughly triangular in shape, with the base along the nasolabial fold and the apex toward the zygomatic prominence. When the malar fat pad descends, it adds fullness to the nasolabial fold and deepens it.

Functional Significance

The malar fat pad must be repositioned to improve midfacial appearance. This may be accomplished with subperiosteal, deep plane, and composite face-lift techniques. With the deep plane lift, the fat pad remains attached to the overlying skin and tension on the skin elevates the cheek.

With age, not only is there descent of the malar fat pad, but also loss of volume. The recent work of Lambros has demonstrated that volume loss may be clinically more relevant than descent. Currently, our approach to facial rejuvenation includes a combination of malar fat pad elevation as well as volume replacement.

Buccal Fat Pad

Anatomic Features

The buccal fat pad lies deep to the deepest of the facial layers and contributes to cheek and facial contour. This specialized type of fat, called syssarcosis, enhances muscular motion. It resembles orbital fat in color, function, and form.

The buccal fat pad is intimately related to the temporalis, masseter, and buccinator muscles, the zygomatic and buccal branches of the facial nerve, and the parotid duct. The space that is occupied by the buccal fat pad is called the masticatory space. The buccal fat pad within this space separates the muscles of mastication from each other and from the mandible, maxilla, and zygoma.

The buccal fat pad weighs approximately 8 to 12 g and consists of a central body and three extensions. The temporal extension extends superiorly deep to the zygoma, the pterygoid extension extends backward deep to the ramus of the mandible, and the buccal extension, which is the most superficial extension, lies within the cheek. The body and buccal extensions are clinically significant and contribute to cheek contour.

The central body is located above the parotid duct and extends along the upper anterior border of the masseter muscle. It lies deep to the masseter muscle and over the upper fibers of the buccinator extending to the maxilla where it lies over the second maxillary molar. Posteriorly it is wrapped around the maxilla.

The buccal extension lies below the parotid duct, which separates it from the central body. Deep to it lie the buccinator and oral mucosa and the facial vessels; the zygomatic and buccal branches of the facial nerve lie superficial to it. The parotid duct passes through the fat pad and buccinator into the oral mucosa opposite the second maxillary molar. The pterygoid portion passes downward and backward on the deep medial surface of the ramus of the mandible lying on the lateral surface of the medial and lateral pterygoid muscles. The deep temporal portion extends upward deep to the zygoma lying directly over the temporalis muscle and its tendon.

Functional Significance

In selected cases removal of the buccal fat pad will reduce cheek fullness and enhance the malar eminence. It is essentially the central body and buccal portion or extension that is clinically removed, effecting contour changes of the cheek.

The buccal fat pad has a distinct yellow color and is easily distinguished from subcutaneous fat. Because of its intimate relationship with the facial vessels, parotid duct, and branches of the facial nerve, the fat should be gently teased and removed. Sharp dissection should be avoided. The buccal fat pad resembles an egg yolk in color as well as in size and consistency; removing this pad from the masticatory space is also reminiscent of separating egg yolk from egg white.

Stuzin et al described the intraoral approach, in which a longitudinal incision is made in the buccal sulcus at the level of the second upper molar, dissection continuing through the buccinator. The buccal fat is enveloped in a fascial layer. This fascial layer is opened and the buccal fat pad is as easily identified and delivered as an egg yolk. Alternatively, during open or endoscopic face lift the buccal fat pad is approached along the anterior border of the masseter muscle. Careful dissection and spreading are recommended to avoid injury to the facial nerve branches. Longitudinal spreading will provide easy access to the buccal fat pad.

The buccal fat pad does change with age. It is most prominent in infants and young children. As the surrounding tissues grow with age, this fat pad becomes less prominent during adulthood. With old age, the buccal fat pad undergoes involution, is far less prominent, and can descend, contributing to the heaviness of the jowls.

The Submental or Digastric Triangle

With greater interest in subplatysmal procedures to improve neck contouring, the anatomy of the submental triangle has gained importance. Two sides of the submental triangle are made up of the anterior belly and posterior belly of the digastric and ramus; the mandible makes up the third side. Within this triangle deep to the platysma lie the subplatysmal fat, the submandibular gland, the facial artery and vein, the lingual nerve, and the marginal mandibular branch of the facial nerve. There are also a number of lymph nodes within this triangle.

Mylohyoid Muscle

The mylohyoids are a pair of flat triangular sheets of muscle originating from the mylohyoid line of the mandible. The fibers run forward and downward toward the insertion, posteriorly into the hyoid and anteriorly into a fibrous raphe that extends from the mentum to the hyoid. These paired muscles compose the muscular support of the floor of the mouth and constitute the medial side of the submental or digastric triangle.

Submandibular Gland

The submandibular gland is a bilobed structure with a large superficial lobe and a much smaller deep lobe. The lobes are attached to each other along the posterior border of the mylohyoid muscle. The bulk of the gland lies under the body of the mandible and extends down to the tendinous junction between the two bellies of the digastric. The gland is encased in a connective tissue capsule. The relations of the superficial part of the gland are as follows:

- Anterior lies the anterior belly of the digastric muscle

- Posterior lie the posterior belly of the digastric and the stylohyoid muscles

- Medial lie the mylohyoid, hyoglossus, and the lingual and hypoglossal nerves

- Lateral lie the body of the mandible, the platysma, and the cervical branch of the facial nerve

- The facial artery crosses the posterior and superior aspect of the gland

Functional Significance

The contents of the submental or digastric triangle all lie deep to the platysma and in neck contouring or rejuvenation constitute the deepest layer of the neck. Removal of subplatysmal fat, partial tangential or complete excision of the anterior belly of the digastric muscle, and partial excision of the superficial lobe of the submandibular gland all constitute deep plane neck procedures and contribute to neck recontouring.

Although fat and digastric muscle excision is relatively straightforward, the excision of the superficial lobe of the submandibular gland may cause concern because of the intimate relationship of the gland to the facial artery, cervical and marginal mandibular branches of the facial nerve, and the lingual nerve. However, since the gland is encased in a sheath or capsule, intracapsular dissection of the gland is relatively safe.

Concluding Thoughts

My fascination with anatomy first began in medical school, when I recognized the beauty and complexity of the body's anatomic structures. I well remember one of my professors telling me that I would learn anatomy three times and forget it four times. Little did I know how true that statement was. Over the span of my career, I have not only learned and relearned my anatomy, but also have grown to recognize that this is a topic that requires frequent revisiting if one is to gain familiarity with anatomic structures, their relationships, and the intricacies of their vasculature and innervation. Perhaps it was this fascination with anatomy that led me into a career as a surgeon. Regardless, it is knowledge of anatomy that is the foundation of all of the surgical procedures that I perform today.

A detailed knowledge of the anatomy of the face is essential to appreciate the aging process and the resulting changes in facial appearance. Armed with this understanding, we can successfully develop strategies for rejuvenation. Understanding of the planes of the face and the contents of each of these planes enables the surgeon to satisfactorily and confidently operate on facial tissues to restore a youthful appearance while minimizing morbidity.

Dissecting with confidence while ensuring the safety of important nerve and vascular structures is the hallmark of an experienced surgeon. With experience, the surgeon also recognizes the fact that variation in anatomy is the rule rather than the exception. Two sides of the same face will vary in symmetry and anatomy, just as the facial anatomy will vary from one individual to another. In addition to naturally occurring anatomic variations, the surgeon must also be prepared to address those resulting from trauma and from previous surgical interventions.

Although anatomy is seemingly static, we would be mistaken to assume that we know all there is to know about this topic. New anatomic insights and details are regularly being described as our understanding of facial anatomy continues to evolve.

Annotated Bibliography

Furnas DW. The retaining ligaments of the cheek. *Plast Reconstr Surg* 83:11-16, 1989.

This article discusses anatomic features and functions of the retaining ligaments of the cheek. With a thorough knowledge of this anatomy, surgical landmarks can be identified and anatomic disorientation during facial dissection can be avoided.

Knize DM. An anatomically based study of the mechanism of eyebrow ptosis. *Plast Reconstr Surg* 97:1321-1333, 1996.

The development of eyebrow ptosis with aging is commonly attributed to progressive laxity of scalp and forehead soft tissues. However, if change in eyebrow position resulted entirely from tissue stretching, uniform lowering of the medial and lateral eyebrow segments should occur. Clinical observations show that the lateral eyebrow segment usually becomes ptotic earlier than the medial segment, indicating that a more complex mechanism exists. To clarify the development of eyebrow ptosis, the author performed anatomic and histologic studies on 20 (40 half-head) fresh cadaver specimens. The studies confirmed that the mechanism producing eyebrow ptosis has a relatively greater effect on the lateral eyebrow segment. The interaction of structures and forces contributing to the mechanism producing eyebrow ptosis is also discussed. Derived concepts can be applied to the execution of the forehead lift procedure.

Knize DM. Reassessment of the coronal incision and subgaleal dissection for foreheadplasty. *Plast Reconstr Surg* 102:478-489; discussion 490-492, 1998.

The subgaleal plane is the most commonly used dissection plane for foreheadplasty to-day. However, some surgeons have begun to advocate using the subperiosteal plane, and controversy surrounds the question of which dissection plane is more surgically sound for raising a forehead flap. On the basis of 25 fresh cadaver dissections and more than 20 years of clinical experience with foreheadplasty, the author concludes that dissection done at the subperiosteal rather than the subgaleal plane provides greater benefit to the patient.

Mendelson BC, Freeman ME, Wu W, et al. Surgical anatomy of the lower face: the premaseter space, the jowl, and the labiomandibular fold. *Aesthetic Plast Surg* 32:185-195, 2008.

The authors describe the premaseter space, an avascular cleavage plane that contains vital structures through which sub-SMAS dissection can be performed safely and easily. They conclude that the premaseter space should be considered the preferred dissection plane for lower (cervicofacial) face lifts.

Mendelson BC, Muzaffar AR, Adams WP. Surgical anatomy of the midcheek and malar mounds. *Plast Reconstr Surg* 110:885-896; discussion 897-911, 2002.

The authors describe the anatomy of the midcheek to explain midcheek aging and malar mounds. Their cadaver study located a glide plane space overlying the body of the zygoma. The function of this space, together with the anatomic boundaries and anatomic features of this area, determine the characteristic aging changes that occur in this region and explain malar mounds. The authors also discuss the surgical implications of this anatomy.

Meyer DR, Linberg JV, Wobig JL, et al. Anatomy of the orbital septum and associated eyelid connective tissues. *Ophthal Plast Reconstr Surg* 7:104-113, 1991.

The authors examine the anatomy of the orbital septum and associated eyelid connective tissues and review embryologic development of the eyelid connective tissues. Recommendations for ptosis surgery based on the anatomic principles discussed are provided.

Mitz V, Peyronie M. The superficial musculo-aponeurotic system (SMAS) in the parotid and cheek area. *Plast Reconstr Surg* 58:80-88, 1976.

The authors investigated the SMAS in the parotid and cheek areas by anatomic dissections, radiographs, and histological sections. They conclude that the SMAS may be helpful in corrective surgery for facial palsy and during face-lift operations if a retrofascial approach is used. However, this procedure, safe in the parotid area, can become dangerous in the area anterior to the parotid gland.

Moss JC, Mendelson BC, Taylor GI. Surgical anatomy of the ligamentous attachments in the temple and periorbital regions. *Plast Reconstr Surg* 105:1475-1490; discussion 1491-1498, 2000.

This study documents the anatomy of the deep attachments of the superficial fasciae within the temporal and periorbital regions. Knowledge of these relationships allows the surgeon to use the tissue planes and soft tissue ligaments as intraoperative landmarks for the vital neurovascular structures. This results in improved efficiency and safety for aesthetic procedures in these regions.

Rohrich RJ, Pessa JE. The fat compartments of the face: anatomy and clinical implications for cosmetic surgery. *Plast Reconstr Surg* 119:2219-2227; discussion 2228-2231, 2007. *The authors investigated the partitioning of subcutaneous fat of the face in multiple independent anatomic compartments by performing 30 hemifacial cadaver dissections. They found that the nasolabial fold is a discrete unit with distinct anatomic boundaries. What has been referred to as malar fat is composed of three separate compartments: medial, middle, and lateral temporal–cheek fat. The forehead is similarly composed of three anatomic units, including central, middle, and lateral temporal–cheek fat. They concluded that the concept of separate compartments of fat suggests that the face does not age as a confluent or composite mass. Shearing between adjacent compartments may be an additional factor in the causes of soft tissue malposition.*

Rohrich RJ, Pessa JE. The retaining system of the face: histologic evaluation of the septal boundaries of the subcutaneous fat compartments. *Plast Reconstr Surg* 121:1804-1809, 2008.

The authors studied the histology of the septal boundaries between several adjacent fat compartments. They found that fibrous condensation of connective tissue formed diffusion barriers. These septa originated from underlying fascia and inserted into the dermis of the skin. A septal barrier originated from the fascia of the frontalis muscle, so these septal barriers are not necessarily related to the superficial musculoaponeurotic system but can occur anywhere between superficial fascia and skin. Their findings support the concept that subcutaneous fat is compartmentalized, specifically by fascial condensations that travel from superficial fascia to dermis. These septa form an interconnecting framework that limits shearing forces on the face. This framework provides a “retaining system” for the human face. Implicit in this concept is the suggestion that the face ages three-dimensionally, with separate compartments changing relative to one another by both position and volume.

Rohrich RJ, Pessa JE, Ristow B. The youthful cheek and deep medial fat compartment. *Plast Reconstr Surg* 121:2107-2112, 2008.

This article explores the concept of pseudoptosis as a mechanism of midfacial aging: diminished volume of a specific deep fat compartment leads to an excess skin envelope and the illusion of a more prominent nasolabial fold. The anatomy of this deep fat compartment, and of two others, is described.

Schaverien MV, Rohrich RJ, Pessa JE. Vascularized membranes determine the anatomical boundaries of the subcutaneous fat compartments. *Plast Reconstr Surg* 123:695-700, 2009.

The authors demonstrate that superficial fat in the face exists in distinct anatomic compartments. These fat compartments are separated by fascial septa that arise from the superficial fascia and insert into the dermis. Perforating vessels arising from deep arteries travel through these septa to supply the skin and define the overlying vascular territories or angiosomes.

Whetzel TP, Mathes SJ. Arterial anatomy of the face: an analysis of vascular territories and perforating cutaneous vessels. *Plast Reconstr Surg* 89:591-603; discussion 604-605, 1992. *The authors investigated the cutaneous arterial circulation of the face and scalp by using multiple anatomic techniques in fresh cadaver specimens. They defined 11 vascular territories of the face and scalp and observed three distinct patterns of arterial vascularization. The results of this study provided the anatomic framework to potentially revise or improve reconstructive or aesthetic procedures of the face based on known arteries.*

CHAPTER 41

Clinical Decision-Making in Face Lift and Neck Lift

FOAD NAHAI

Evaluation

Not all faces age in the same way, nor do they require the same procedures for rejuvenation. The degree of volume loss, tissue descent, and skin changes will vary. Each face ages individually, with some areas remaining more youthful than others. I evaluate the entire face, assessing skin quality, volume, and descent. For descriptive purposes, I think of the face in terms of the three zones: periorbital, perioral, and neck.

The forehead, brow, and upper midface make up the *periorbital zone*; the lower part of the face—nasolabial folds, lips, jowls, and chin—is called the *perioral area*; and the jawline, submental area, and neck are referred to as the *neck zone*. I also think of these three zones as dividing the face and neck into upper, middle, and lower thirds.

Ideally, I prefer to rejuvenate all three zones simultaneously to restore a youthful appearance with a harmonious transition from zone to zone. Most of the time, however, patients request improvement in one zone or only one component of a given zone. Many patients who would be excellent candidates for full facial rejuvenation say, “I just want my eyes or my neck done.” Another typical request is, “I know I could use a face lift, but I just want to get rid of my baggy eyelids.” These patients require an explanation of the aging process so they will understand that it is best to

address an entire zone rather than individual components of a zone. It is even better to address all three face and neck zones rather than only one. Nevertheless, some patients truly need rejuvenation of only one zone rather than of the full face. In these patients, the aging process has advanced more rapidly in one zone than in the others.

In this 56-year-old patient, aging affected all three of the facial zones. She underwent an endoscopic brow lift, upper and lower blepharoplasty, and face and neck lift. Her postoperative result demonstrates harmonious rejuvenation of all three facial zones.

The signs of aging are not as far reaching in this 48-year-old patient. Her facial aging was confined mostly to the upper third, or periorbital zone. She underwent an endoscopic brow lift and upper lid blepharoplasty with transpalpebral midfacial rejuvenation. Her postoperative result also demonstrates harmonious facial rejuvenation, even though the surgical correction was far more limited.

When a patient expresses interest in a procedure involving only one zone, I advise her or him about how the overall result could be enhanced by adding procedures involving adjacent zones. Doing so avoids a patchwork effect in which a rejuvenated periorbital area leads into an aging lower face and neck. The patient's motivation for seeking less rather than more may be financial, or could be related to a fear of surgery and anesthesia, or the patient may have a genuine lack of concern about the rest of the face compared with the area in question. The surgeon should initiate an open discussion of the patient's wishes, concerns, and fears so the patient will be pleased rather than disappointed with the results. When examining a candidate for face-lift surgery, I first determine which zones require intervention and whether the aging process has affected the face equally. For example, is the most striking feature of this aging face the neck, the midface, or the brow? Or are they all equally involved?

Facial aging involves more than sagging, wrinkling skin with shifting soft tissue; most of these patients have also lost volume. An aging face in a thin patient looks much older than an equally aged full face in an overweight patient. This is obviously related to loss of volume. After my initial impression, I evaluate the skin, each zone, and the components of each zone according to my mental checklist.

Facial Skin

The evaluation includes an assessment of skin quality and skin excess, along with the presence of rhytids at rest and on animation. I look for signs of photoaging and sun-related dyschromia. I assess the skin's thickness and elasticity and make a mental note of where the excess skin is and whether the excess is real or apparent.

Checklist for Evaluating the Aging Face—Facial Skin

Quantity	Quality	Rhytids
<i>Visible skin excess</i>	<i>Thickness</i>	<i>At rest</i>
	<i>Elasticity</i>	<i>On animation</i>
	<i>Photoaging</i>	

This 50-year-old woman has facial aging in all three zones. Her skin quality is rather poor, showing real and apparent excess skin, significant photoaging, and deep rhytids at rest and on animation.

This 51-year-old patient also demonstrates facial aging in all three zones but has better skin quality. Her full, heavy face has more apparent than real excess skin, normal elasticity, and minimal photoaging. No rhytids are visible at rest.

Upper Third of the Face: The Periorbital Zone

Evaluation of the periorbital zone begins with an analysis of the medial and lateral brow position and the relationship of the brow to the upper eyelid. I look at the glabella for lines as well as active and passive rhytids. The temporal brow junction, with the upper cheek–zygomatic area, is evaluated for the presence of deep rhytids (crow’s-feet) and excess skin (see Chapters 27 and 35). I evaluate the upper and lower lids, assessing the skin, muscle, and fat in the lids. After noting the relationship of the upper lid to the brow, I move to the lower lid, noting the relationship of the lower lid to the cheek and the transition from the periorbital to the perioral zone. Lower lid tone is assessed. The volume of the cheek and midface area is also noted.

Checklist for Evaluating the Upper Third of the Face/Periorbital Zone

Brow position	Lower eyelid
<i>Lateral</i>	<i>Skin</i>
<i>Medial</i>	<i>Muscle</i>
Glabella	<i>Fat</i>
<i>Depth of rhytids</i>	<i>Lid-cheek junction</i>
<i>Muscle activity</i>	<i>Lid tone</i>
Upper eyelid	Nasolabial folds
<i>Skin</i>	Transition to perioral zone
<i>Muscle</i>	Soft tissue volume
<i>Fat</i>	
<i>Relationship to brow</i>	

Middle Third of the Face: The Perioral Zone

The perioral area, or middle third, is evaluated next. The nasolabial folds and marionette grooves are categorized by noting their depth at rest and when smiling (see Chapter 9). The angle of the mouth is noted. The lips are evaluated for volume and length of the upper lip. With aging, the lips lose a significant amount of volume and the distance from the nose to the upper lip vermilion lengthens, leading to a loss of definition of the philtral columns. Lip lines are noted. I specifically look at the depth of the chin crease for chin ptosis and evaluate the jowls. I also evaluate the role of the mandibular ligament in the aging appearance in this area. The nose, especially the tip, often becomes ptotic with aging.

Checklist for Evaluating the Middle Third of the Face/Perioral Zone

Nasolabial folds and marionette grooves	Lower lip
Angle of the mouth	<i>Volume</i>
<i>Downward</i>	<i>Lip lines</i>
<i>Neutral</i>	Chin
<i>Upward</i>	<i>Chin crease</i>
Upper lip	<i>Chin ptosis</i>
<i>Volume</i>	Jowls
<i>Length</i>	Nose
<i>Philtral columns</i>	<i>Tip ptosis</i>
<i>Lip lines</i>	

Lower Third of the Face: The Neck Zone

In assessing the quality and quantity of the neck skin, I look for excess skin below the thyroid cartilage and over the sternocleidomastoid muscle. A judgment is made as to whether the submental skin excess is real or apparent. I then look at the jawline, submental area, and neck-jaw angle and their relationship to each other. Assessment of the submental and neck fat includes the subcutaneous fat and the subplatysmal fat. I differentiate between subcutaneous and subplatysmal fat by pinching the submental area at rest and then after contraction of the platysma muscles.

Checklist for Evaluating the Lower Third of the Face/Neck Zone

Skin	Fat
<i>Quality</i>	<i>Subcutaneous/preplatysmal</i>
<i>Quantity</i>	<i>Subplatysmal</i>
– Real excess	<i>Platysma bands</i>
– Apparent excess	<i>Jawline</i>
	<i>Neck/jaw angle</i>
	<i>Digastric muscles</i>
	<i>Submandibular gland</i>

Evaluation of excess skin of the neck and platysma bands with the patient at rest

Evaluation of platysma bands on animation

Evaluation of the location of submental fat, pinching the submental area at rest

Subcutaneous versus platysma fat is assessed by pinching the submental area during contraction

The platysma bands are evaluated. The submandibular gland and digastric muscles are assessed by looking for a bulge below the mandibular rim within the submandibular triangle, especially on neck flexion.

Facial Adhesions and Retaining Ligaments

Determining whether the facial ligaments and adhesions should be released is an important step in planning surgical rejuvenation of the face.

Proper elevation and rejuvenation of the periorbital area depends on the appropriate release of a number of temporal adhesions and attachments, regardless of the degree of brow ptosis or facial aging. In contrast to the face, these temporal adhesions and attachments are not visible and cannot be assessed clinically.

Retaining ligaments of the midlateral face can be assessed clinically. These ligaments maintain the facial skin in its normal anatomic position. Stuzin et al described two types of retaining ligaments: a true osteocutaneous ligament running from a fixed bony origin to the dermis (such as zygomatic and mandibular), and a second system made up of a coalescence of superficial and deep facial fascia fixing the fascial layers to the underlying structures, such as the parotid and masseter, and then attaching superficially to the skin (the parotid cutaneous and masseteric cutaneous ligaments). These ligaments are essentially fixed structures so that facial tissue, especially fat pads, can pivot around them, producing creases such as the marionette lines of the lower face. With age, the ligaments attenuate and relax. This relaxation, along with loss of skin elasticity and soft tissue, causes some of the stigmata of aging. The zygomatic ligaments suspend the malar soft tissues and fat pad over the zygomatic

prominence. As this support weakens, the malar soft tissues gradually migrate downward, and redundant skin hangs over the fixed nasolabial sulcus. Rather than deepening with age, it is the downward migration of the soft tissues against the fixed nasolabial sulcus that accounts for the observed changes. Similarly, attenuation and weakness of the masseteric cutaneous ligaments allow a downward shift of the cheek tissues below the mandibular margin. Tethering by the mandibular ligament forms the jowls.

Clinical evaluation of the face should take note of these ligaments and the role they play in the aging face. Ligaments extending from bone to dermis must be released during a face lift to achieve the desired results. Leaving the masseteric ligaments intact limits lateral mobility. An evaluation of the relevance of these ligaments to the observed aging changes allows the surgeon to plan appropriately for ligament release. Although release of these ligaments is required in most older individuals, it is not always necessary to divide them in younger individuals and in those undergoing limited rejuvenation procedures.

TREATMENT OPTIONS

The Face

I do not believe that there is a face lift for all seasons. However, all described face-lift techniques have five things in common:

1. An incision
2. Flap elevation
3. Vectors
4. Fixation
5. Ancillary procedures

Evaluation of the face leads to selection of the procedure including length and location of the scars, level and extension of dissection or flap elevation, management of the superficial musculoaponeurotic system (SMAS), vectors, volume management, and ancillary procedures. These decisions are based on analysis of the patient's degree of aging, morphology, skin quality and quantity, and, most important, the patient's expectations and my understanding of the anticipated result.

The options include a variety of incisions, different levels of dissection, varying extent of skin undermining, different vectors, and repositioning of the subcutaneous tissues through a number of suspension or plication techniques.

Treatment Options for the Face

Incisions	Extent of skin undermining
<i>Length</i>	SMAS management
<i>Location</i>	<i>Plication</i>
Levels of dissection	<i>Resection and plication</i>
<i>Subcutaneous</i>	<i>Mobilize, resect, and plicate</i>
<i>Subfascial</i>	Vectors
<i>Subperiosteal</i>	<i>Vertical</i>
<i>Combination</i>	<i>Diagonal</i>
	Suspension sutures

Incisions

The length of the incisions varies from liposuction and endoscopic access incisions to the classic full-length face-lift incision. The purpose of skin incisions is to gain access to deeper tissues, resect excess skin, or both.

If the purpose of the skin incision is to allow access to the deeper tissues, and the deep tissue rearrangement renders the desired result without skin excision, these access incisions can be kept to a minimum, as in liposuction and endoscopic procedures. If the desired result cannot be attained through the rearrangement of the deeper tissue without skin excision, a longer skin incision is necessary, and the length of that skin incision will reflect the location of the excess skin to be removed. For example, endoscopic face lifting is achieved without removing any facial skin, whereas short-scar face-lift techniques eliminate the postauricular scar in patients who have no excess skin below the level of the cricoid and posterior to the sternomastoid. However, the success of endoscopic and short-scar procedures depends not only on the location of excess skin but also on the quality and elasticity of the skin. These procedures rely on redraping and redistribution of the skin, especially in the neck. Stretched, inelastic skin, regardless of location—face, breast, or abdomen—will not redrape, redistribute, or retract and must be excised.

The short-scar techniques have increased in popularity as patients demand minimally invasive procedures, with less down time and reduced morbidity. Patient selection is the key, because unless a less-invasive procedure with a shorter scar produces a result comparable to that of standard procedures, is not in the best interest of the patient and may result in loss of the surgeon's credibility. In selecting patients for the short-scar technique, I assess the quality of the neck skin and then evaluate the patient with what I call the "vertical simulation" test. I place my hand on the

side of the patient's face in front of the tragus and pull vertically upward, simulating the vertical vectors of the short-scar face lift. While my hand is elevating this tissue, I observe the junction of the earlobe and neck skin. If there are no folds of excess skin extending posteriorly beyond that area, the patient is an excellent candidate for a short-scar face lift. If there is excess skin or if a fold develops there, the patient is best suited for a full-scar procedure. Additionally, this test also enables me to evaluate the neck and submental area and determine whether I will make a submental incision or not by observing the neck during the vertical simulation test.

For example, these images depict an ideal candidate for a short-scar face lift. The vertical vector, as demonstrated by the examiner's hand, does not result in any folds of excess skin behind the earlobe, and the improvement seen in the submental area obviates the need for a submental incision.

In contrast, these images show an individual who would not be a candidate for a short-scar face lift, because the vertical vector demonstrated by the examining hand results in folding of excess skin beyond the earlobe, and the lack of improvement in the submental area and jawline indicates the need for a submental incision and a central approach to neck recontouring.

Location

The scar location depends on the patient's facial structure, including the hairline, sideburns, skin color, and ear topography.

Temple Incision

Incision behind the temporal hairline

Prehairline incision

The options include placement of the incision 2 to 3 cm behind the temporal hairline or right at the temporal hairline. This decision is based on the distance between the lateral canthus and the anterior part of the temporal hairline, which ideally should be 3 to 5 cm. To maintain this ideal distance, the excess skin over the upper cheek is assessed. This excess skin will be recruited and rotated upward when the face-lift flap is elevated. If resection of excess cheek skin through the incision behind the temporal hairline would widen the distance between the hairline and lateral canthus, I prefer a prehairline incision to maintain a natural 3 to 5 cm distance. Widening beyond 5 cm results in an unnatural or “operated-on” appearance. When resection of the excess cheek skin would not shift the temporal hairline posteriorly or widen the distance between the hairline and lateral canthus, the incision can safely be placed behind the hairline. This placement is of more significance in men than in women.

Incision behind the temporal hairline

Prehairline incision

In patients with short sideburns, I prefer the prehairline incision to avoid elevation or elimination of the sideburns through the vertical shift of facial skin. In secondary face lifts I make a prehairline incision, because most of these patients already have shortened sideburns.

Preauricular Incision

The incision in the preauricular area is made in the anatomic margin between the ear and the face rather than in front of it. Not only the color but also the texture and thickness of the ear skin vary from that of facial skin.

To mask this difference, a curved incision along the curve of the anterior border of the helix is made to the upper border of the tragus. At this juncture, the incision may be curved in front of the tragus or along the posterior border of the tragus; then it fol-

lows the sulcus between the earlobe and the cheek. My preference is for the intratragal incision along its posterior border but not behind the tragus. A well-executed intratragal incision is imperceptible compared with a pretragal incision. In the rare patient who has little color difference between the facial and tragal skin, the pretragal incision may serve as well. For a tragal incision to be imperceptible, the tragus has to have a beginning and an end and not blend into the cheek at the lower border. The inferior tragal border must be preserved. The prominence of the tragus plays a role in selecting the intertragal incision. The more prominent the tragus, the better the rest will be. A flat tragus may retract forward and lead to enlargement of the external auditory meatus. Special attention must be paid in men, whose facial skin may be ruddier than the ear skin. In these patients a pretragal incision is preferred.

Retroauricular Incision

A high retroauricular incision crossing to the hairline—best suited to individuals with modest redundancy of neck skin with normal skin elasticity

A lower retroauricular incision crossing to the hairline—best suited to individuals with modest to excessive redundancy of neck skin with some loss of skin elasticity

An occipital hairline incision—best suited to individuals with excessive or massive skin redundancy, especially in the lower neck with stretched, inelastic skin

I used to make retroauricular incisions only in patients with inelastic or stretched neck skin with excess skin below the cricoid and posterior to the sternomastoid, but now I rely on the vertical simulation test to determine the need for a retroauricular incision. This incision is best placed within the retroauricular sulcus. The upward length is not only a matter of personal preference but of practical importance. I vary it according to my estimate of the amount of skin to be removed. The less skin that is being removed, the longer I make this retroauricular incision before taking it transversely across into the occipital hairline. In patients with an excessive amount of redundant skin, I take this incision across to the occipital hairline and then follow it downward. I discuss these options with patients so they understand the incisions are being altered to achieve a better result.

Choosing the Best Option

Features	Face Lift: Incision Options		
	Prehairline	Prehairline With Discontinuous Temporal Incision	Temporal Continuous With Preauricular Incision
Sideburns			
High or short			
Low or long			
Hairline			
Anterior: Lateral canthus to hairline distance 3 to 5 cm			
Posterior: Lateral canthus to hairline distance >5 cm			
Secondary Face Lift			

Levels of Dissection

Subcutaneous

I personally do not perform a subcutaneous face lift and believe that few surgeons do. The subcutaneous dissection serves two purposes: access to deeper tissues (SMAS) and skin resection. All modern face-lift techniques include various degrees of skin undermining. Extensive skin undermining to release the nasolabial fold and mandibular retaining ligaments, although effective, can increase the risk of vascular compromise and hematoma.

Subfascial

Most modern face lifts include some form of subfascial or sub-SMAS dissection. The extent of this dissection varies from technique to technique. The vectors and methods of plication also vary from surgeon to surgeon. I rely heavily on SMAS mobilization and a vertical vector for improvement of the perioral area, jowls, and jawline.

Low dissections of the SMAS have a limited effect on the upper midface and periorbital area. High SMAS dissections dramatically improve the upper midface and periorbital area.

In thin faces, I try to preserve the SMAS; in heavy faces, I resect it. I plicate the SMAS or undermine and plicate as necessary. My preference is to incise the SMAS not immediately preauricular, as in some described techniques, but at the junction of the mobile and fixed SMAS. This avoids dissecting the very thin SMAS in the preauricular area. My decision to plicate or to mobilize and plicate the SMAS depends on its mobility. I pick the SMAS up at the junction of the fixed and mobile SMAS and pull it superiorly while observing the effect on the jawline and perioral area. If the pull provides the desired effect, I simply plicate (in thin faces), or resect and plicate (in heavy faces). However, if pulling without mobilization does not produce the desired effect, I incise and mobilize the SMAS until the desired effect is observed.

Subperiosteal

The advantage of the subperiosteal approach to the midface is its relative ease, speed, and safety. The facial nerve branches are less at risk with this approach; however, it is limited in its effects on the lower face, jawline, and jowls. The subperiosteal approach depends on suspension sutures to maintain the result.

Combinations

The subperiosteal and subfascial or subperiosteal and subcutaneous levels of dissection can be combined in a variety of ways. Examples include a subperiosteal approach to the periorbital area and midface and a sub-SMAS approach to the perioral area and jawline.

Vectors

Most modern face lifts include a separate vector for the skin and deeper tissues. The deeper tissues are elevated in a more vertical or diagonally vertical vector and the skin in a more posterior and vertical direction. The vertical vector on the SMAS improves the jawline, the perioral area, and, with the high SMAS technique, the midface. The more diagonal vector on the platysma improves on the neck and submental area. With a short-scar face lift, the skin vector is vertical, but the vector on the SMAS and platysma can be varied.

Choosing the Best Option

Regional Effects	Face Lift: Levels of Dissection						Suspension Sutures and Devices
	Subcutaneous	Subfascial				Subperiosteal	
		Standard SMAS	High SMAS	Extended SMAS	SMASectomy		
Periorbital	+	+	++++	++	++	++++	++++
Cheek and nasolabial folds	++	++	++++	++++	++++	++++	++++
Jowls and jawline	++	++++	++++	++++	++++	+	+
Neck		++	+++	+++	+++	+++	
Vectors	Diagonal	Vertical	Vertical Diagonal	Vertical Diagonal	Vertical Diagonal	Vertical Diagonal	Diagonal Diagonal
Risks							
Skin flap viability	++++	++	+	+	+		
Facial nerve	+	++	++++	++++	++		

Degree of effectiveness indicated by the number of pluses.

Sutures

Suspension

Most endoscopic and subperiosteal midface techniques require suspension sutures or other devices to elevate and hold the soft tissues in the desired position. Although usually effective, these sutures are not risk free; a disadvantage is that the fixation point is far removed from the tissue being fixed.

Ancillary Procedures

Ancillary procedures include volume management and resurfacing. These are performed almost routinely in all of my facial rejuvenation procedures to enhance the overall result. Although in the past the actual face lift was the end result, today many of us feel that the face lift lays the foundation, and the ancillary procedures that are performed concomitantly represent the finishing touches that result in true rejuvenation rather than simply the rearrangement of soft tissues.

Volume Management

Although volume management usually includes augmentation of tissues, in selected patients I also remove excess volume, especially in the neck and jowls. Alloplastic implants, autologous fat, and fillers are available for volume enhancement. By far the most popular material of choice for volume enhancement is autologous fat. In some patients, volume enhancement with fat transfer has become routine. Alloplastic materials such as chin and cheek implants may be preferable to fillers or autologous fat in selected patients. Fillers are also an acceptable alternative to autologous fat for volume enhancement.

The buccal fat pad is very prominent in some heavy faces and must be addressed to recontour the perioral area and jawline. The buccal fat pad can be approached either through the face-lift incision deep to the platysma or through an intraoral incision. I have resected the buccal fat pad as an isolated procedure in heavy, youthful faces (those that present a cherubic appearance) and in primary as well as secondary face lifts for recontouring. Despite the intimate relationship of the superficial portions of the buccal fat pad with the facial nerve, I have found this procedure to be both safe and effective. Although I rarely resect the buccal fat pad, in the right patient it has a dramatic effect in recontouring the lower face and managing volume.

It is rare and only in a heavy face that I resect fatty tissue. When I do so, it is limited to the jowls. However, in all but the thinnest of necks I resect some fat below the skin, between the platysma or deep to the platysma, depending on the volume of the neck and distribution of the fat in these three layers.

Resurfacing

Rearranging the deep tissues and resecting excess skin does not always result in improvement of the quality of the skin. Sun-damaged, inelastic, wrinkled skin is usually dealt with through resurfacing, concomitant with the face lift. This includes dermabrasion, peels (croton oil or TCA), and lasers. These procedures, when combined with a face lift, are not only effective but also safe if limited to the areas where there has been no skin undermining. The undermined skin may also be treated with dermabrasion, peel, or laser, but cautiously and very superficially. Judgment must be exercised on an individual basis when resurfacing over face-lift flaps.

The Neck

Treatment Options for the Neck

Incisions	Extent of skin undermining
<i>Length</i>	Vectors
<i>Location</i>	<i>Vertical</i>
Levels of dissection	<i>Diagonal</i>
<i>Subcutaneous</i>	Suspension sutures
<i>Subplatysmal</i>	Plication sutures

Incisions

Length

Incisions for rejuvenation and recontouring of the neck range from liposuction access incisions to submental incisions and preauricular and retroauricular incisions. Incision length is dictated by the anatomic and morphologic findings as well as the planned procedure. The submental incision allows access to the medial platysma and subplatysmal structures. The retroauricular incision allows access to the lateral platysma and affords the opportunity for skin resection.

Location

SUBMENTAL My preference for the submental incision, varying in length from 3 to 5 cm, is to place it just posterior to the submental crease. Others prefer to place the incision within the crease. I believe placement within the crease further deepens the

crease and attracts attention to the scar. Posterior placement affords better access to the submental area and allows dissection anteriorly to eliminate or render the submental crease less shallow. This incision also allows access to the chin for correction of the ptotic or “witch’s” chin.

RETROAURICULAR In the isolated neck lift without a face lift, it is sometimes necessary to begin the incision at or below the level of the tragus, continuing around the earlobe and into the retroauricular area to prevent earlobe distortions and improve access to the jawline and neck. In the past I typically reserved retroauricular incisions for patients with inelastic or stretched neck skin with excess skin below the cricoid and posterior to the sternomastoid, but now I rely much more on the vertical simulation test. The best placement is within or just above the retroauricular sulcus. Upward length should be varied according to the amount of skin removal required. The less skin to be removed, the longer I make this vertical component before crossing to the hairline. If neck skin is excessive, I place the incision along the occipital hairline in a downward and backward direction rather than extending it into the hair. These incisions are all planned preoperatively, and their location and alternatives are fully discussed with the patient. I emphasize the benefits of a lower incision in terms of tightening the lower neck skin.

Choosing the Best Option						
Features	Neck Lift: Incision Options					
	Preauricular	Submental	Short in Retroauricular Sulcus Only	Longer Above Level of Tragus Crossing Into Hair	Long to Level of Tragus Crossing Into Hair	Long to Just Below Level of Tragus Then Crossing Down Along Occipital Hairline
Skin Quality						
Normal elasticity						
Inelastic, stretched, sun damaged						
Skin Quantity						
No skin excess						
Apparent skin excess						
Real skin excess						
Planes of Intervention						
Superficial						
Deep to platysma						

Levels of Dissection

Planes of the Neck
Superficial plane
Intermediate plane
Deep plane

I think of the neck as having three planes: superficial (skin and subcutaneous fat), intermediate (platysma and interplatysmal fat), and deep (subplatysmal structures).

Superficial Plane

The superficial plane includes the skin and subcutaneous fat; each neck and submental lift includes varying degrees of dissection and undermining in this plane. It is important to leave at least a 3 to 5 mm thickness of fat on the deep surface of the skin, whether the defatting is performed directly or through liposuction. Leaving this layer of fat with a suitable thickness renders a smooth contour to the neck and eliminates the skin irregularities that are seen with aggressive removal of subcutaneous fat. Aggressive removal of fat leads to adherence of the skin onto the platysma. Intervention in this plane is usually combined with interventions in the other two planes, except in individuals who are candidates for liposuction only.

Intermediate Plane

The platysma and the small amount of fat between the medial border of each platysma muscle make up this plane. Plication of the platysma in the midline is the most common procedure at this level. In a patient with a heavy submental area, the intervening fat between these medial borders is resected as necessary. If fat is resected from between the platysma muscles and deep to the platysma, it is important that sufficient fat be left deep to the skin. Removing fat aggressively below the skin, between the platysma muscles and deep to it, leads to an unnatural hollowing of the submental area. Very rarely do I remove fat from all three layers. The more deep fat I remove, the more superficial fat I leave behind.

Deep Plane

The subplatysmal fat, digastric muscles, and the submandibular gland make up the structures of the deep plane. Resection of the subplatysmal fat, the anterior belly of the digastric muscle, and the superficial lobe of the submandibular gland are the procedures performed in this plane. If needed, a suprahyoid fascial release is also performed in the deep plane.

To distinguish between excessive preplatysmal (subcutaneous) fat and subplatysmal fat, a useful maneuver is to grasp the submental fold between the thumb and index finger and then ask the patient to grimace, thus contracting the platysma muscles. If the fold between the examiner's thumb and index finger is unchanged, the bulk of the fat is subcutaneous; if it diminishes, then the bulk of the fat is deep to the platysma and must be removed in that plane to recontour the submental area.

Once the subplatysmal fat has been dissected, the anterior belly of the digastric muscle is easily viewed. If it appears as a bulge when the patient's neck is flexed, a tangential excision of the anterior belly would further improve the submental contour.

A large submandibular gland is often visible preoperatively. Once the digastric muscle has been identified, the superficial lobe of an enlarged submandibular gland is readily visible. If it bulges further on neck flexion, the superficial lobe can be resected to further enhance neck contour and improve on the visible bulge.

Extent of Skin Undermining

With the exception of liposuction only, extensive neck undermining is the rule to facilitate the redraping of the apparent excess skin of the neck, especially in the submental area. The undermining usually extends from the sternomastoid muscle on each side, across the midline, and down to the level of the thyroid cartilage. More extensive lateral and inferior dissection and undermining may be necessary in some individuals who have an excessive amount of neck skin or inelastic skin.

Choosing the Best Option

Planes or Layers of the Neck	Neck Lift: Incisions and Anatomic Features								
	Incisions		Fat Distribution			Structures			
	Liposuction Access	Submental	Subcutaneous	Interplatysmal	Deep or	Platysma	Digastric Muscles	Sub- mandibular Gland	Hyoid Fascia
					Subplatysmal				
Superficial									
Intermediate									
Deep									

Vectors

The vectors that influence the appearance of the neck and jawline include the vertical vector applied to the jawline through the platysma plication of a face lift. A more diagonal and posterior vector involving the lateral border of the platysma combined with a medial plication of the two platysma muscles defines the submental area and the neck-jaw angle.

Sutures

Suspension Sutures

Suspension sutures running over the platysma and below the mandibular border, designed to define the neck-jaw angle, were described by Guerrerosantos and later popularized by Giampapa. In carefully selected patients, suspension sutures can be effective, but I have found them to be of limited value in individuals with large submandibular glands. In my experience, a more direct approach in the deep plane produces longer-lasting results.

Plication Sutures

Plication of the platysma in the midline, as advocated by Feldman (the corset platysmaplasty), is highly effective in recontouring the submental area. When combined with a lateral plication, platysmal plication defines the jawline and neck-jaw angle. This step is an integral part of almost all the neck lifts I perform.

Ancillary Procedures

Although volume management in the neck almost always means removal of fat or partial resection of the digastric or submandibular gland, volume addition in the form of autologous fat or acellular dermal matrix has been advocated for correction of the contour irregularities associated with aggressive oversuction superficial to the platysma. Resurfacing either with laser or my preference, TCA peels, is an acceptable adjunct to neck lift. The energy levels on the laser are set below that for a face lift. I apply 20%, 30%, or even 50% TCA to the face, but I limit neck peeling to 20% TCA, and even then the endpoint is a mottled frosting rather than the uniform frosting that I look for on the face.

CHAPTER 42

The MACS-Lift Short-Scar Rhytidectomy With Fat Grafting

PATRICK L. TONNARD, ALEXIS M. VERPAELE

When different surgical techniques in facial rejuvenation are compared, one is tempted to focus on the result without considering the global risk-benefit ratio associated with any surgical intervention. Some techniques can produce superb results, but the trade-off may be a high complication rate or a prolonged postoperative recovery. Today, many patients prefer a simpler route to rejuvenation. Bearing in mind that the ultimate goal of aesthetic surgery is a happy patient, it is not always the most aggressive and extensive surgery that delivers the greatest patient satisfaction. Ultimately, it is the delicate subjective balance between the final result and the morbidity of the procedure that will determine the level of patient happiness. The appeal of the *minimal access cranial suspension lift* (MACS-lift) lies primarily in the fact that it strikes the right balance, offering a stable, natural facial rejuvenation through a simple and safe procedure. The operation takes only 2 to 2½ hours to perform and can be done with a local anesthetic in an outpatient setting. In comparison with a classic face lift, the MACS-lift has a quicker recovery time and a lower morbidity rate, with a final scar that is significantly shorter.

The MACS-lift provides a powerful correction of submental and upper neck laxity, correction of a blunted submental angle, restoration of a well-defined jawline by correction of the jowls, restoration of the midfacial volume, and correction of the nasolabial folds. Patients who are seeking improvement of one or more of these features are good candidates for a simple or extended MACS-lift procedure. Adjunctive procedures to enhance the results may include upper and lower blepharoplasty, micro-fat grafting, short-scar temporal lifting, and anterior and posterior cervicoplasty.

Basic Concepts

Traditional face-lift designs all have an oblique vector of traction on the superficial musculoaponeurotic system (SMAS), which can be divided into a horizontal and a vertical component. In recent years, more emphasis has been put on reorienting this vector in a more vertical direction.

In classic face-lifting, the direction of skin redraping still follows an oblique vector. The horizontal component of the vector of traction on the SMAS and on the skin does not rejuvenate the face; rather, it tends to flatten the face and put it under tension.

With the MACS-lift, the vertical rejuvenating vector is the only vector applied on the deep tissues as well as on the overlying skin. The MACS-lift eliminates the horizontal vector of traction; it can therefore be considered a pure vertical vector face-lift technique.

When lateral skin redraping is performed, as in classic face lifts, a dog-ear is created at the earlobe, necessitating redraping with a retroauricular flap dissection. No dog-ear is produced under the earlobe with vertical skin redraping, thus obviating the need for retroauricular dissection. Therefore the MACS-lift can also be considered a purely antigravitational procedure.

The MACS-lift is aimed at obtaining an antigravitational volume redistribution in the upper neck and face by suspending the soft tissues of the face, working in the superficial subcutaneous plane without any deeper undermining. The skin excess is redraped in a vertical direction and resected in the temporal region and lower eyelid.

In recent years the concept of volumetric rejuvenation has gained worldwide acceptance. We now know that the restoration of facial volumes is more important than the amount of skin resected and the tension on the skin and SMAS. There are many methods to obtain this volumetric restoration; the question remains: In what plane should the surgery be done to obtain a good result while minimizing morbidity? The MACS-lift technique provides a safe and effective method for accomplishing these goals. This technique acts directly on the sagging soft tissues, with suspension sutures in the superficial subcutaneous level and limited skin undermining, to provide an efficient, safe, and durable correction with significantly lower morbidity and faster recovery.

Overview of Technique: Simple and Extended MACS-Lift

The key concept underlying the MACS-lift procedure is the vertical suspension of sagging facial soft tissues with slowly resorbable monofilament purse-string sutures. These are strongly anchored to deep temporal fascia through a preauricular and temporal prehairline incision. Excess skin is excised in the temporal region after pure vertical redraping of the skin flap. Submental suction lipectomy always precedes the lifting procedure. The extent of the skin undermining is just sufficient for placing the purse-string sutures. There are two variations of the procedure:

The *simple MACS-lift* (S-MACS), in which two purse-string sutures are placed for correction of the neck and the lower third of the face (cervicomental angle, jowls, and marionette grooves)

The *extended MACS-lift* (X-MACS), in which a supplementary third purse-string suture is placed to suspend the malar fat pad; this suture will have an added impact on the nasolabial groove, midface, and lower eyelid

Simple MACS-Lift

With the simple MACS-lift approach, the incision begins at the lower limit of the earlobe, extends preauricularly to the temporal hairline, and traces the temporal hairline along the sideburn up to the level of the lateral canthus. The skin is undermined at a subcutaneous level over 5 to 6 cm in an anterior direction. The inferior limit of undermining goes as caudal as necessary to visualize the lateral border of the platysma muscle. Usually the undermining is marked 2 to 3 cm below the mandibular angle.

The first purse-string suture is anchored to the deep temporal fascia 1 cm in front of the helical rim and 1 cm above the zygomatic arch. It runs downward toward the mandibular angle as care is taken to incorporate a firm bite in the craniolateral border of the platysma muscle, and then it turns upward as a narrow U-shaped loop toward the original anchor point. The suture is firmly woven into the SMAS tissue, which is not undermined. When this purse-string suture is tightened, the lateral portion of the platysma is pulled upward. This suture, when combined with a closed-suction lipectomy, produces a dramatic correction of the cervicomental angle and contour of the upper neck.

The second purse-string suture starts at the same anchor point on the deep temporal fascia, extends more obliquely toward the jowls (± 30 degrees from the first suture), and follows the borders of the undermining as a more open, O-shaped, purse-string loop. It ends at the original anchor point. When this suture is tightened, the SMAS is placed under concentric tension, producing a lift to the jowl, the marionette groove, and the corner of the mouth.

Extended MACS-Lift

The incision for the extended MACS-lift follows the same course as in the simple MACS-lift but is extended in a cranial direction for 1 to 2 cm along the anterior temporal hairline, up to the level of the tail of the eyebrow. The skin is undermined as in the simple MACS-lift, but a supplementary area over the malar fat pad is included.

The third purse-string suture has a narrow U-shape, like the first one. Its anchor point is located in the most anterior part of the deep temporal fascia, just lateral to the lateral orbital rim. This suture runs first downward toward the malar fat pad, then turns back toward the anchor point. Tightening this suture serves to suspend the malar fat pad, thereby correcting the nasolabial groove and midface ptosis and shortening the height of the lower eyelid.

In both the S-MACS and X-MACS procedures, after placement of the sutures, the skin is redraped in a purely vertical direction and the excess skin above the temporal hairline incision is resected without any traction. Because there is no lateral traction on the skin, there will be no dog-ear at the level of the earlobe, eliminating the need for retroauricular dissection. This is contrary to the classic face-lifting concept in which skin is redraped in a more oblique direction, generating a skin excess below the earlobe that needs to be redraped further backward through a retroauricular flap dissection.

As a consequence of lifting the malar fat pad toward the lateral orbital rim, the skin “bunches up” in the region of the lateral part of the lower eyelid and the paracanthal zone. This necessitates a skin excision in the subciliary and paracanthal region. Because of the good structural support of the lower eyelid provided by the third purse-string suspension suture, this pure skin resection is easy and safe. The excess skin is evaluated by pinching the skin between the teeth of a forceps and is excised through a lower eyelid blepharoplasty incision with paracanthal extension (the pinch blepharoplasty). The surgeon can easily resect 4 to 8 mm of skin, especially in the paracanthal region, without risk of causing ectropion or scleral show.

The MACS-lift will adequately treat 90% of our patient population. When the limits of the MACS-lift procedure are reached, ancillary procedures will supplement this procedure. Care is taken not to overtreat any patient.

Ancillary Procedures

Anterior Neck

Preoperatively, the patient's facial and cervical flaccidity is assessed by the surgeon by digitally lifting the facial skin upward at the mandibular angle region. If this maneuver produces correction of visible platysma bands, one can be confident that the MACS-lift will adequately tackle this problem. If the platysmal bands are not corrected with this preoperative maneuver, an anterior cervicoplasty is added at the end of the MACS-lift procedure. Because suturing together platysmal bands on the midline counteracts the lifting effect on the cheeks, the neck work is delayed until the face-lift procedure is completed. At the end of a MACS-lift procedure, the lateral parts of the platysma are so tightly pulled upward by the vertical purse-string sutures that it is virtually impossible to bring the medial borders of the platysma together to the midline. Therefore we prefer an open resection of the medial bands of the platysma at the end of the procedure. A resection of about 1 cm of medial muscle border is carried out, with or without a horizontal relaxation incision at the level of the hyoid. Conservative open resection of subplatysmal fat is done when indicated.

Posterior Neck

The limits of MACS-lifting depend on the amount of skin excess in the neck as well as the quality of the skin. Problems can arise when dealing with thin, sun-damaged neck skin with a significant amount of wrinkles down to the clavicular region. In these cases, after vertical skin redraping, vertical skin folds will begin to appear in the infralobular neck region. These folds are aesthetically unacceptable and need to be corrected at the end of the procedure with a posterior cervicoplasty (see p. 1407). This maneuver consists of tension-free redraping of the skin in an occipital direction from a prehairline posterior neck incision.

Forehead

Indications for brow lifting are very surgeon dependent. Some surgeons believe that everyone needs one; others—and we fall into this category—are more conservative in their approach and do not routinely elevate every patient's eyebrows.

Many procedures are available for forehead correction, ranging from open foreheadplasty to endoscopic brow lift or limited incision temporal lifting techniques. With the introduction of *botulinum* A toxin into our practice, our indications for surgical brow-lifting have diminished impressively. Almost every patient is offered *botulinum* toxin treatment after surgery. It completes the treatment, optimizes the result, and leads to improved patient satisfaction.

Indications and Contraindications

The MACS-lift short-scar technique is particularly appropriate for younger patients who usually are not willing to undergo aggressive and potentially risky procedures to achieve their goals. It is also suitable for older patients who do not want to change too much, but only want to obtain correction of their obvious signs of aging. For these patient populations, less aggressive but still effective surgical rejuvenation techniques are welcome.

The ideal patient for a surgeon's initial MACS-lift case is a 45- to 50-year-old woman whose main complaint is a moderate submental laxity with a blunted cervicomental angle, but without visible platysmal bands. Jowls, marionette grooves, and nasolabial folds are developing but are mainly disturbing to the patient when she bends forward. This is a frequent complaint in middle-aged women who discover these signs of aging in the lower third of the face. This type of patient is ideally suited for treatment with the two-suture simple MACS-lift technique.

This patient's mild jowling and central anterior neck laxity make her an ideal candidate for correction by a simple MACS-lift.

The extended MACS-lift, with the addition of a third suture, is particularly appropriate for a patient who needs correction of the upper half of the nasolabial folds and the midface. The third suture suspending the malar fat pad gives a powerful correction of these features and also enhances the volumetric restoration of the midface, providing very strong support to the lower eyelid skin. Therefore the indication for the third suture can be extended to patients of all ages who have a flattened malar mound and laxity of the lower eyelids. The need for the third suture is not only determined by age, but also by the bony anatomy of the face. A person with a poorly developed malar eminence will be subject to earlier midfacial aging than one with a strong malar relief. This is also often related to poor lower lid support.

Both of these women would benefit from an extended MACS-lift. For a younger patient, it will correct the malar insufficiency and flattening of the lateral cheek. In an older patient, it will also correct the nasolabial folds and midfacial hollowing.

In classic teaching, smoking is considered an absolute contraindication for face-lift surgery. Because of the limited subcutaneous dissection and the absence of multiplanar dissection, we consider smoking to be a relative contraindication. For the same reason, combining the MACS-lift with skin resurfacing techniques is safe and well tolerated.

As a general rule, only patients with no major medical history of disease or cardiovascular risk factors are selected for outpatient, office-based surgery. The decision whether to perform the MACS-lift with a local or general anesthetic depends on the surgeon's and patient's preferences.

Pertinent Anatomy

Three permanent purse-string sutures are woven into the deep subcutaneous tissues, which consist of parotid fascia and SMAS in the preauricular area, and the malar fat. The sutures are anchored into the deep temporalis muscle fascia to ensure a strong hold.

The main danger zone in the placement of sutures is located on the zygomatic arch, halfway between the ear and the lateral orbital rim. This zone is completely avoided, because no suture crosses the zygomatic arch. The anchor point of the first two sutures is located posterior to the frontal branch of the facial nerve. The first loop is directed vertically downward and reaches the lateral edge of the platysma muscle in the region of the mandibular angle. The marginal mandibular branch of the facial nerve is out of danger for entrapment by the purse-string suture, since it runs more anteriorly.

The second purse-string suture loop runs at an angle of 25 to 30 degrees and reaches to 1 to 2 cm above the mandibular border. The third loop takes its origin in the temporalis muscle fascia just lateral to the lateral orbital rim and is also directed downward. It lies well anterior to the course of the frontalis branch of the facial nerve.

Preoperative Assessment

Generally, it is very important to listen carefully to the patient's wishes in the first clinical consultation. We start by inquiring what bothers the patient and has prompted this visit.

When asked what they are seeking, most patients consulting for facial rejuvenation demonstrate a maneuver that they have repeatedly executed before their mirrors: they push the skin of the mandibular angle upward. This maneuver has a beneficial effect on the neck and on the jowling. Some patients also include the zygomatic region into this maneuver and push it upward. This will have an additional effect on the nasolabial fold, the midface, and the lower eyelid.

The main consideration when assessing a potential candidate for MACS-lift surgery is determining whether a simple or an extended MACS-lift is indicated. A simple MACS-lift acts primarily on the lower half of the face—the upper neck and submental area, jowls, marionette grooves, and lower cheeks.

This 52-year-old woman exhibits moderate fatty deposits in the submental area with jowling and marionette grooves. There is a slight downward slant of the corners of the mouth. She has a somewhat heavy neck, which will require maximal power-assisted liposculpture (PAL) for contouring. Her malar area has well-preserved defi-

nition, and there is no obvious skeletonizing of the lower eyelid. Treatment will consist of submental liposculpture combined with a simple MACS-lift to correct the neck laxity, jowl deformity, and marionette grooves. (Her results can be seen on p. 1418.)

This 56-year-old woman had general sagging of the lower part of the face with a lax, fatty, infiltrated neck with obvious platysmal bands, marked jowling, deep nasolabial folds and marionette grooves, and pronounced nasojugal grooves with demarcation of the inferior orbital rim. A simple MACS-lift would improve her neck, jowls, and marionette grooves, but to adequately address her midface, an extended MACS-lift with a third purse-string suture to the malar area is needed. This would restore a youthful ogee curve to the cheek, correct the upper nasolabial folds, refill the lower orbital rim, and correct the nasojugal grooves. Her planned treatment consists of a submental liposculpture, an extended MACS-lift, and a lower pinch blepharoplasty. (Her postoperative result is shown on pp. 1426-1427.)

It is important to explain the concept of the MACS-lift intervention to the patient. To do this, it is helpful to simulate the feasible correction on the facial features with the patient looking in the mirror and the physician standing behind. This will give the patient an idea of the possibilities and limitations of the technique. The patient will learn that the MACS-lift is a lifting procedure that addresses the neck and lower two thirds of the face, without having an influence on the forehead. The patient will also understand that the main goal is to restore the facial volume and to get rid of most of the facial laxity.

It is rare for a patient to demand an extreme correction at the risk of a completely flattened, expressionless face. *Patients want to look younger, not different.* Many patients are afraid of changing too much and losing facial expression. In the majority of patients, it is perfectly feasible to reproduce the desired result with the MACS-lift procedure. In some cases, ancillary procedures can be proposed, but the patients must be informed of the cumulative morbidity to be expected. Once the surgeon understands the patient's expectations, a treatment plan can be designed to meet patient goals. The patient's input is essential to this process.

All patients are fully informed of the details of the proposed procedure, including the benefits, limitations, risks, time of surgery, expected morbidity and recovery, and the potential for problems and complications. This informed consent is provided both verbally and in written documents given to the patient.

Preoperative Planning

Photography

A standardized series of nine pictures is taken of the patient.

The frontal view shows the face from the top of the head down to the sternal notch.

A perfect perpendicular side view should show only one eyebrow, with the patient gazing straight forward.

The oblique view has the tip of the nose just within the contour of the opposite cheek to demonstrate the distribution of the facial volumes.

An extra side view picture is taken with the patient looking down at the knees, producing a double chin. We refer to this as the “Bruce Connell view,” because he has pointed out its importance.

A close-up view of the lower face is taken to focus on the contour of the jaw line, marionette grooves, and nasolabial folds and to demonstrate any perioral rhytids (the “bar code”). A close-up view of the upper half of the face reveals detailed information about the upper and lower eyelids, tear troughs and periorbital fold, grooves and wrinkles.

Patient Instructions

The patient is instructed to take the following medications:

Oral ampicillin 500 mg every 6 hours, beginning the morning of surgery and continuing for 4 days

Acyclovir 800 mg once daily for 10 days, beginning 2 days preoperatively, if erbium-YAG laser resurfacing is performed

Arnica montana 30K for prevention of ecchymoses and edema, of which five doses are taken:

- 1 week preoperatively
- 1 day preoperatively
- Immediately before surgery
- Immediately after surgery
- 1 day postoperatively

Continue any home medication

The patient is instructed to respect the following guidelines:

Stay in the company of a friend or relative for the first 24 hours.

Relax in a quiet environment.

Avoid stressful activities.

Avoid bending forward and Valsalva maneuvers.

Sleep with the head slightly elevated.

A soft diet is recommended, since mouth-opening is painful the first 5 days because of traction on the temporalis muscles.

Dressing instructions after resurfacing include the following:

Avoid allowing the resurfaced area to dry out by regularly applying copious amounts of Vaseline/paraffin ointment at least every 2 hours.

Gently remove the ointment every 4 hours, then apply a gauze soaked in a solution of tepid tap water and vinegar (1 coffee spoon of vinegar to 1 coffee cup of tepid water).

Do not remove the yellowish, fibrous exudate that covers the wound for 4 to 5 days.

It will disappear spontaneously as the skin heals.

The patient is also informed about normal postoperative discomfort, swelling, and ecchymosis, especially in the eyelids. He or she is instructed to contact the surgeon if any of the following conditions develop:

Rapidly increasing swelling and/or pain in the cheek area, which could indicate a postoperative hematoma

Pain or increasing discomfort in the resurfaced area

A temperature greater than 38° C (100.4° F)

Any visual impairment

Operative Technique

Preoperative Markings

Any makeup is removed by the nurse and a new set of nine pictures is taken. The patient sits upright in front of the surgeon for the initial markings. Submental liposuction is planned for almost every patient. Fat tends to accumulate in this area, so even in slim patients, liposuction in this region helps to enhance the cervicomental angle.

The patient is asked to make a double chin, and the area where excess fat is palpated is marked with a pencil (*left*). Care is taken to include the lateral “wings” of the submental fat, which go as far as the infralobular area, and the lower pole of the jowls.

When the nasolabial folds, midface, and/or lower eyelids require correction, an extended MACS-lift is planned. This necessitates extra preoperative marking to guide the placement of the third suture.

A point is marked 2 cm caudal to the lateral canthus (*right*). In most people this point coincides with the bulk of the malar fat pad. During surgery this point will be suspended by the third suture to the most anterior part of the deep temporal fascia, just lateral to the lateral orbital rim. An arrow is marked between the two points and is repeated on the contralateral side.

Anesthesia and Surgical Setting

We prefer to perform the MACS-lift using a local anesthetic with sedation. If the surgeon prefers, heavier sedation can be used, but patient cooperation will diminish and oxygen must be administered. This procedure can also be performed with the patient under general anesthesia, depending on the surgeon's preference.

The MACS-lift is designed to be performed, ideally, in a private surgical office by one surgeon and one nurse. If the instrument table is well prepared in advance, no circulating nurse is necessary. A headlight or a lighted retractor is required for placement of the purse-string suture beneath the cheek flap. The height of the operating table must be controllable by foot switch, and the surgeon's seat must also be adjustable in height by nonsterile foot manipulation.

Submental Infiltration

The sequence of infiltration follows the sequence of the procedure:

1. Upper eyelids
2. Submental area
3. Cheek infiltration

For a submental suction lipectomy, an average of 30 to 40 ml is infiltrated in the preplatysmal fat until a moderate degree of tumescence is achieved.

Markings and Incisions

With the patient supine on the operating table, marking resumes at the lower limit of the lobule, extending up in the preauricular crease. The incision is usually carried out on top of the tragus. At the level of the incisura intertragica, the marking makes a 90-degree turn backward to preserve the integrity of this anatomic landmark. Markings then follow the posterior edge of the tragus, ascending toward the helical root. Because there is a distinct color difference between the cheek skin and the auricular skin, it is essential that the markings precisely follow this line of demarcation. At the superior limit of the ear, the marking traces the small hairless recess between the sideburn and the auricle and then turns downward to follow the inferior implantation of the sideburn.

In men, the marking descends approximately 1.5 cm before turning anteriorly to cross the sideburn.

The horizontal marking then continues forward in a zigzag pattern 2 mm within the lower and anterior implantation of the sideburn. This zigzag pattern increases the length of the temporal incision for better congruence with the length of the cheek flap. In a simple MACS-lift the incision will extend to the level of the lateral canthus. In an extended MACS-lift the incision goes up to the level of the tail of the eyebrow (*note dotted line*). The total length of the incision will not exceed 7 to 9 cm, depending on the dimensions of the auricle (vertical branch of the incision) and the width of the sideburn (horizontal branch of the incision).

The surgeon palpates the mandibular angle with an index finger and marks it as the lowest point of the undermining. The extent of the undermining is marked starting from the lowest point of the incision at the lobule, directed toward the marking of the mandibular angle, then curving anteriorly to 5 to 6 cm in front of the ear. Next, the marking is directed toward the upper end of the incision. For an extended MACS-lift, the preoperative marking of the malar eminence should be incorporated. If a simple MACS-lift is planned, the malar eminence is not included in the demarcation.

When adjunctive procedures are planned (such as an upper/lower blepharoplasty, fat grafting, short-scar temporal lifting, anterior/posterior cervicoplasty), they are marked together with the MACS-lift markings. (For detailed descriptions, see the individual adjunctive procedures later in this chapter.)

The subcutaneous plane is infiltrated with the preferred solution of local anesthetic. Normally 30 to 40 ml of solution is injected in the cheek, which gives a moderate degree of tumescence. At the end of the cheek infiltration, a distinct blanching is visible in the previously infiltrated eyelid and submental areas.

Suction Lipectomy

We prefer to use a 3 mm spatula cannula with one opening. The opening is always directed downward, not toward the skin, to avoid dermal damage. Two or three incisions are used to crisscross the marked area optimally. The lipectomy is performed in a preplatysmal plane under tactile guidance of the nondominant hand. A maximal lipectomy is performed so that in the end the cannula is visible just beneath the skin. For patients with heavy necks, power-assisted liposuction (PAL) is used. It enhances patient comfort, since the cannula movements are less vigorous, especially when the patient is under local anesthesia. It also diminishes the physical effort for the surgeon.

Incision

The incision starts at the lobule and continues along the previously described markings. The surgeon carefully respects the incisura intertragica by making a distinct 90-degree step at the beginning of the tragus.

The tragal incision is made exactly on the edge of the tragus. An incision placed too anterior to the tragus will leave a visible color difference between the pale tragus skin and the slightly darker cheek skin.

The blade is then inclined to an angle of 30 degrees to the skin so the incision goes obliquely through the dermis, perpendicular to the hair shafts. The incision follows the marked zigzag pattern 2 mm within the hairline.

An oblique incision within the hairline will allow hair to grow through the scar. After hair regrowth, the final scar will be hidden a few millimeters within the hairline and become virtually invisible.

Flap Creation

Blind undermining of the skin is performed with Rees face-lift scissors, and the dissection proceeds in a subcutaneous plane. The scissors points are directed toward the skin to ensure that the surgeon has visual and palpable control over the thickness of the cheek flap. Most of the dissection is accomplished by spreading maneuvers with the scissors. Care is taken to create a flap sufficiently thick to mask small irregularities of the underlying layer.

After the flap is created, hemostasis is achieved by direct coagulation with microneedle cautery under direct illumination by a lighted retractor or a headlight.

First Purse-String Suture: The Vertical Loop

The initial purse-string suture will be fixed to the deep temporalis fascia at a point 1 cm above the zygomatic arch and 1 cm in front of the helical rim. (The zygomatic arch is marked for demonstration purposes.) An extra dose of local anesthetic is injected at the anchor point (*note dot*) down to the temporal bone, then the needle is withdrawn and all layers of tissues are infiltrated.

With the iris scissors in the spreading mode, a 0.5 cm diameter window is made in the subcutaneous tissue to visualize the deep temporal fascia. It should be identified as a distinct, white, shiny layer. A 2-0 permanent suture on a big V-7 needle is used to perform the suspension of the sagging facial and neck soft tissues. A Prolene, Gore-Tex PTFE, or Mersilene suture can be used.

The first bite starts in the window where we visualize the deep temporal fascia and goes down to the temporal bone. The needle is oriented toward the tragus, so there is no danger of damaging any facial nerve branch. The frontal branch of the facial nerve runs deep in this region and becomes superficial several centimeters more anteriorly. Firm bites approximately 1 to 1.5 cm long and 0.5 cm deep are taken in the SMAS tissue—parotid fascia in the upper two thirds and platysma in the lower third. With every bite it is essential to confirm that the needle enters a substantial part of the SMAS tissue so the suture will not pull through.

The suturing goes down toward the region of the mandibular angle to the lower limit of the undermining. In this region direct visualization by means of a headlight or a lighted retractor is helpful.

When the region of the mandibular angle is reached, the suturing is turned upward and continued toward the starting point.

This creates a narrow U-shaped purse-string loop about 1 cm wide. (The course of this loop is marked on the patient for demonstration purposes.) After the first purse-string suture is tied, some obvious skin dimples might occur at the mandibular angle. Most of these will disappear with the vertical redraping of the skin, but some will have to be freed with scissors.

Second Purse-String Suture: The Oblique Loop

The second suture originates from the same location on the deep temporal fascia. This purse-string suture forms a wider loop, directed toward the jowls, at an angle of ± 30 degrees with the vertical. This loop is more O-shaped than the U-shaped vertical loop to prevent linear traction on the subcutaneous tissue, which could be visible through the skin.

The loop follows the borders of the anterior undermining in the lower part of the cheek. Short bites of 1 cm maximum are taken in the parotid fascia and the SMAS tissue.

Third Purse-String Suture: The Malar Loop

The first and second sutures start from a common anchor point 1 cm above the zygomatic arch and 1 cm anterior to the helical rim. (The projection of the three purse-string sutures has been marked on the patient's skin for orientation and demonstration purposes.) The third suture has a separate anchor point on the deep temporal fascia, just lateral to the lateral orbital rim. Here a window is made in the orbicu-

laris muscle by spreading the iris scissors. This suture forms a narrow U-shaped loop to prevent bulging of subcutaneous tissue in the highlighted zygomatic area. It runs to the malar fat pad, which has been preoperatively located by a point marked 2 cm below the lateral canthus.

With the same suture (2-0 Prolene, Gore-Tex, or Mersilene), a deep bite is taken to anchor the suture to the deep temporal fascia. The purse-string suture is oriented obliquely downward and medially. The malar fat pad is recognizable by a more fibrous consistency than the surrounding subcutaneous fat. At the preoperatively marked point—the malar fat pad—the direction of the suturing is reversed, now in upward and lateral direction. The loop has a narrow U-shape, grabbing firm parts of tissue with every bite of the suture. The suture ends at its starting point in the window made in the orbicularis muscle.

The knot is tied under maximal tension. The window in the orbicularis muscle is closed with 4-0 Vicryl to prevent knot palpability in the lateral orbital region. Again, some skin dimples may have to be freed with the scissors at the borders of the malar undermining.

Skin Redraping and Resection

One of the most important features in the short-scar face lift is the vertical redraping of the skin. This provides a “lock” to the subcutaneous sculpturing work in the cheek. Because the vector of the subcutaneous lifting is almost purely vertical, the redraping and resection of the skin in the same direction will seal the underlying suspension effect. Vertical redraping also prevents formation of dog-ears at the lobule. The earlobe is pulled upward by the suspension sutures and will have to be set back in the cheek flap, taking the place of any dog-ears.

When vertical redraping of the skin is performed, the need for retroauricular skin redraping will be avoided or limited to the few cases with extreme neck skin laxity.

The skin flap is put under moderate vertical tension, and the skin excess is determined with the help of the Pitanguy-d'Asumpção forceps. The skin marking is incised with the knife, and the excess is excised with the scissors. The skin resection on the cheek flap is carried out in linear fashion and will be sutured to the zigzag border of the temporal hairline incision. The zigzag incision will now open up when coapting with the linear cheek flap, thereby compensating for the incongruence in length of both borders and reducing possible dog-ears. Closure with interrupted 4-0 Vicryl buried sutures is started from the superior end of the incision backward to avoid dog-ears in this section.

The lateral part of the cheek flap is trimmed only minimally just to coapt with the preauricular incision. Absolutely no traction is exerted on this part of the incision. The skin is incised with the knife, and the flap is resected with the scissors. The earlobe is pulled upward by the action of the suspension sutures and the redraping of

the skin in the vertical direction. To put the earlobe back into its natural position, a small segment of skin has to be excised anterior to the earlobe. It is preferable to underresect rather than to overresect in this area to avoid postoperative position changes of the earlobe.

The horizontal limb of the incision is sutured with a running 5-0 nylon horizontal mattress suture, taking bigger bites on the cheek flap side than on the temporal side to compensate for the final incongruence in length between both sides.

A small, hollow, silicone tube is inserted for drainage at the lowest point of the incision. This tube will drain into the loose retroauricular dressing during the first 24 hours postoperatively, after which it is removed, together with all dressings. The rest of the suturing is done with running and separated 6-0 nylon sutures.

Adjunctive Procedures

Pinch Lower Blepharoplasty

A pinch lower blepharoplasty is routinely added after performing an extended MACS-lift, because the lifting of the malar mound creates skin excess in the lower eyelid region. The concept of the pinch blepharoplasty of the lower eyelid is to safely remove excess skin in the paracanthal and lateral subciliary region after providing strong structural support of the lower eyelid through suspension of the malar fat pad with the third purse-string suture of the MACS-lift procedure.

The skin excess is estimated by a pinching maneuver with a nontoothed forceps and marked with methylene blue. The pinch blepharoplasty is performed through a classic lower blepharoplasty incision.

The skin is freed from the orbicularis, vertically redraped without any tension, and resected.

One or two inverted 5-0 Vicryl buried subcutaneous sutures are placed in the canthal and paracanthal part of the incision. The skin is closed with a running 5-0 nylon intradermal suture.

Posterior Cervicoplasty

One of the consequences of vertical redraping of the skin is that in some patients, aesthetically unacceptable vertical folds appear in the infralobular region. This occurs primarily in patients with extreme neck laxity and thin, elastotic, wrinkled neck skin, which is typically associated with severe sun damage. In our series this represented 2% of cases. (This procedure was not performed on the patient whose case presentation began on p. 1389 and whose postoperative care is detailed on pp. 1426-1427, but was performed on the patient described on pp. 1430-1431.)

A 5 cm incision is designed in a zigzag pattern at the occipital hairline. The area of skin undermining is designed to reach 1 cm beyond the anteriormost infralobular skin fold. The skin flap is created by blind scissors dissection in a superficial subcutaneous level.

The skin is redraped in an occipital direction, and the skin excess is resected. The skin is approximated with buried 4-0 Vicryl sutures and finished with a running 4-0 nylon horizontal mattress suture over a hollow silicone drainage tube (*arrow*).

Short-Scar Temporal Lift

The goal of face-lift surgery is to turn back the hands of time, rejuvenating the patient's appearance, delaying the process of aging, and restoring a look more like the individual appeared at a younger age.

When analyzing a patient's photographs in her twenties and thirties, the vast majority of photos show full upper eyelids, with only a minimal show of the eyelid above the cilia. The medial part of the eyebrow usually is relatively low, and the lateral third is at the same level or even higher than the medial third.

With aging, the tail of the eyebrow descends to a variable degree, depending on the underlying anatomy of the frontalis muscle. The part of the population that has a frontalis muscle insertion extending to the tail of the eyebrow will have less descent of this part of the eyebrow and often will respond very well to a chemodenervation with *botulinum* toxin of the temporal portion of the orbicularis oculi muscle.

However, most people do not have good support of the lateral third of the eyebrow and develop a degree of temporal hooding with time. It is this deformity that we aim to correct with the short-scar temporal lift. Additionally, when a vertical face lift of any kind is performed, the problem of temporal hooding is aggravated by a gathering of skin in the paracanthal region. This can be anticipated in the preoperative consultation with the patient in front of the mirror. If too much skin redundancy appears in the paracanthal area when simulating the vertical lift, the patient is counseled about the necessity of a temporal lift.

To address these problems, a modified Fogli's temporal lift by fasciapexy is performed. The principle of this operation is basically the same as for a subcutaneous forehead lift, limited to the lateral third of the forehead, in which the galea is used as a vehicle to suspend the ptotic temporal tissue and provide a tension-free skin closure in the temporal hair-bearing skin.

Technique

The subcutaneous part of the temporal undermining is performed from the MACS-lift incision in continuity with the subcutaneous cheek skin undermining. It stops at a level at least 2 cm above the tail of the eyebrow.

The temporal lift is done after the loop sutures are placed, but before the final re-draping and resection of the cheek and lower eyelid skin to reduce the dog-ear formation in the temporal and paracanthal region.

Markings

When a temporal lift is planned in combination with a MACS-lift, the markings are adapted, so that the subcutaneous dissection of the cheek is extended over the temporal region to a level at least 2 cm above the tail of the eyebrow. The skin incision is marked horizontally in the temporal hair-bearing skin.

From here a subgaleal undermining is performed downward to a level about 2 cm above the tail of the eyebrow.

Here the galea is transected with the tip of the scissors from deep to superficial, to fall into the subcutaneous undermining already performed earlier. This maneuver protects against possible damage to the frontal branch of the facial nerve, which runs at the undersurface of the temporoparietal fascia, about 2 cm cranial to the tail of the eyebrow.

Two U-shaped Vicryl 2-0 sutures are placed between the cranial edge of the transected galea and the galea at the site of the skin incision.

Tying these knots will produce a bulging of skin that will disappear after 6 to 8 weeks when the Vicryl sutures lose their strength. After the knots are firmly tied, a few millimeters of skin are resected to minimize skin bulges and the incision is closed with 3-0 running nylon suture.

For the medial part of the forehead, *botulinum* toxin therapy is recommended, because it is an effective way of treating glabellar and frontal grooves without the need for further surgical procedures.

Microfat Grafting

Deflation through loss of subcutaneous fat is a recognized causative factor in facial aging. Guided by early patient photographs (age 20 to 30), we decide which areas need volumetric restoration by additional fat grafting. Experience has taught us that almost every patient loses volume in the nasojugal and nasolabial folds and marionette grooves. About 50% of these individuals will benefit from adding volume to the malar area and the medial upper eyelid.

Technique

Fat grafting is performed before the MACS-lift. This minimizes the cold ischemia time of the prepared fat grafts. At this stage there is also no distortion of the face by edema resulting from the surgery.

The fat is usually harvested by the assistant at the time of infiltration of local anesthetic to the face. The abdomen is the preferred donor site because of its ease of access. A multiholed grater cannula (Tulip; Wells Johnson, Tucson, AZ) with 1 mm sharp holes is used for fat harvesting. The fat parcels harvested this way are small enough to be placed with a 0.9 mm or 0.7 mm grafting cannula.

The fat is then strained through a sterile nylon cloth and rinsed with normal saline solution. Then the fat is collected in 10 cc syringes for final transfer to 1 cc Luer-Lok syringes.

The fat is injected using 0.9 to 0.7 mm diameter blunt cannulas with one small hole on the side. No incision is needed to insert the cannula. A puncture with an 18-gauge needle works well. The puncture hole need not be closed.

Areas for Fat Grafting

The medial part of the upper eyelid is grafted deep to the orbicularis oculi muscle in contact with the interior aspect of the superior orbital rim.

The malar area is grafted very deep, in contact with the malar bone, so that no grafted fat is encountered when the skin is being undermined over the lateral part of the malar area in an extended MACS-lift.

The nasolabial fold is filled in a deep plane, after which a subcision is performed with an 18-gauge needle. Additionally, a small quantity of fat (approximately 0.5 cc) is injected in the cavity created by the subcision to prevent reattachment of the skin to the deeper plane. Intradermal injections are made into vertical perioral, nasolabial and glabellar rhytids and sometimes in the corners of the mouth. This is only possible with the use of the ultrafine microfat parcels harvested with the method described.

Injection Guidelines

Grafted Area	Level of Injection	Volume (cc)
Upper eyelid	Deep	0.8-2.0
Malar	Deep	3.0-25.0
Nasolabial fold	Deep and superficial and intradermal	1.0-3.0
Perioral	Superficial and intradermal	1.0-4.0
Marionette grooves	Deep and superficial	1.5-3.0

Lip Lift Combined With Laser Resurfacing of the Perioral Region

In many persons the vertical height of the upper lip increases with age, hiding the upper incisors and sometimes even covering a part of the lower teeth. Lifting the upper lip has a very rejuvenative effect, especially when combined with microfat grafting.

The excision is planned as a subnasal gull-wing or bullhorn pattern down to the level of the orbicularis oris muscle. No skin undermining is performed. Meticulous closure with 5-0 subcutaneous polylactic or polydioxanone sutures and 6-0 horizontal mattress nylon sutures is performed.

In combination with perioral micrografting, the results of skin resurfacing with an erbium-YAG laser can be significantly enhanced. For the patient on p. 1414, we combined subcutaneous and intradermal microfat grafting with laser resurfacing and lip lift. The depth of the ablation can be reduced when appropriate filling of the rhytids is done by intradermal microfat injection.

Postoperative Care

The area of the neck where liposuction was performed is supported with an adhesive elastic tape. The preauricular incision is covered with a transparent adhesive foil dressing (OpSite, Tegaderm).

Cooling of the skin with ice has been abandoned because of the rebound postoperative vasodilation that occurred. Instead we now use a temperature-controlled cooling device (Hilotherm) that has closed-circuit cooled water circulation through a snug facial mask. The water temperature is set on 15° to 17° C (59° to 63° F). This is sufficient to diminish the facial edema without causing discomfort, while avoiding postcooling rebound swelling. Our clinical experience has shown significantly reduced postoperative swelling and bruising. There is usually some swelling in the superior sternocleidomastoid region; the patient is reassured that this temporary deformity will resolve over the next 2 weeks.

Suction drains and submental adhesive tape are removed on the first postoperative day; the patient is allowed to shower and shampoo. Sutures are removed on postoperative day 6, and any remaining ecchymoses can be concealed with camouflage makeup.

This patient, who is the subject of the operative series on pp. 1393 through 1405, is seen here 24 hours after surgery. At that time the submental adhesive tape, all dressings, and the silicone drainage tube were removed. The undermined area was gently milked out in the direction of the lobule to remove any residual serosanguineous fluid. Usually some swelling in the superior sternocleidomastoid region is apparent; this is often described by the patient as a “bull neck.” The patient is reassured that this temporary deformity will resolve over the next 2 weeks. From this point on the patient is allowed to shower and shampoo daily.

The patient returned 1 week postoperatively for suture removal. Postoperative edema has resolved significantly. Some ecchymoses are still visible, which can be concealed with camouflage makeup.

Preoperative

2 weeks postoperatively

6 weeks postoperatively

Two weeks postoperatively, edema and ecchymoses have almost completely subsided, which allows the patient to return to normal professional and social activities. The sternocleidomastoid swelling has also disappeared, but the patient will still note some mild tension in the temporal region. The patient is informed that this may take 2 months to disappear completely.

Six weeks postoperatively, correction of jowling, marionette grooves, and nasolabial folds is obvious. On frontal view, note the general volume shift in a cranial direction, resulting in a triangularization of her face. On lateral view, note the volume reduction in the submental area, with correction of the cervicomental angle. No folds or dog-ears are visible near the lobulus, confirming the futility of a retroauricular incision in this case. The axis and position of the auricle are unchanged in the vertical as well as in the horizontal direction.

Results

Simple MACS-Lift

This 52-year-old woman was discussed earlier in Preoperative assessment (p. 1387). Her correction was performed under local anesthesia with intramuscular sedation.

Surgical Plan

A simple MACS-lift
Submental liposculpture

The results are seen 1 year after surgery. Note the correction of the cervicomental angle and jowling, as well as the triangularization of her face and better definition of the jawline, which is best seen on the oblique view.

This 50-year-old woman presented with mild corrugator frown lines, correctly positioned eyebrows, and a discrete upper blepharochalasis. She complained of deep nasolabial folds, the downward slant of the corners of her mouth, and beginning laxity of the upper neck.

Surgical Plan

A simple MACS-lift

Botulinum toxin injections to the corrugator, procerus frontalis, and orbicularis oculi muscles

Upper blepharoplasty with resection of skin and muscle and removal of fat from the medial compartment

Submental liposculpture

Seen 1 year postoperatively, the patient shows a softening of the nasolabial folds, correction of the marionette grooves and the downward slant of the corners of the mouth, better definition of her jawline, and a tighter upper neck.

Extended MACS-Lift

This 63-year-old woman presented with facial aging, including facial deflation, sagging, and perioral rhytids. The general shape of her face was rectangular; her eyebrows were in the correct position. She had an apparent skin excess in the upper eyelids, caused by a combination of deflation of the medial part of the eyelid and descent of the tail of the eyebrow. She had baggy lower eyelids, with a moderate skin excess and a marked nasojugal groove. The midface was mildly deflated, especially in the suborbital area. There was a degree of midface ptosis marking the upper third of the nasolabial fold. In the lower third of the face, there were fine rhytids on the upper and lower lip, a downward slanting of the oral commissures, and marked marionette groove and jowling. The laxity in the neck was discrete.

Analysis of the photograph in her early twenties reveals a youthful oval shape to her face. The eyebrows are in a low horizontal position. The upper eyelids are full, with little marginal show. The lower eyelid is taut, with a smooth transition between eyelid and cheek skin and therefore there is no nasojugal groove. She has no nasolabial folds and smooth perioral skin. The jawline is clear, with no jowls or marionette grooves.

Surgical Plan

Extended MACS-lift
Short-scar temporal lift
Discrete upper skin blepharoplasty
Lower blepharoplasty with arcus marginalis release and fat redraping, with discrete skin excision at the end of the procedure
Microfat grafting in the medial part of the upper eyelid (2 cc), malar area (7 cc), nasolabial fold with subcision, including intradermal injection (2 cc), upper lip, including intradermal injection (2.6 cc), and lower lip, including intradermal injection (2.6 cc)

Her results 1 year postoperatively show a restoration of the youthful oval shape of her face. The tail of the eyebrow is slightly elevated, and the upper and lower eyelids have regained their youthful fullness. The sharp shadows of the nasojugal and nasolabial folds and marionette grooves are effaced. The perioral rhytids have disappeared without the use of any resurfacing technique. The jawline is again straight and well defined, and the neck contour is improved.

This 46-year-old woman presented with combined deflated and ptotic facial features. There was a discrete ptosis of the eyebrow tail, with significant hollowing of the upper eyelid. The lower eyelid was empty, without significant laxity. The midface was deflated and ptotic, resulting in a heavy nasolabial fold. The corners of the mouth continued into an incipient marionette groove. The definition of the jawline was disturbed by marked jowling. She also requested a reduction rhinoplasty.

Analysis of her photograph in her late twenties reveals a general oval shape of her face. The youthful fullness of the upper eyelids and midface is striking compared with the empty look in her forties. Note the absence of nasojugal and nasolabial folds and marionette grooves in her earlier photo.

Surgical Plan

Extended MACS-lift
Short-scar temporal lift
Microfat grafting of the medial upper eyelid hollow (1.5 cc), the malar and infraorbital area (10 cc), the nasolabial fold with subcision (3 cc), the marionette groove (2.5 cc); in total, 34 cc of fat grafted
Pinch lower blepharoplasty
Open rhinoplasty

The results after 1 year show a replenishment of her eyelids and midface, with a general triangularization of her face as a result of the cranial shift of soft tissue volumes. The nasolabial folds, marionette grooves, and jowls have corrected. Note the resemblance to her youthful photo.

This 49-year-old man requested facial rejuvenation. He had thick, heavy skin and generalized facial sagging. He has some fatty infiltration of the submental area and ptotic jowls, with deep nasolabial folds and heavy overlying grooves. The midface had descended, and there was a distinct crease between the cheek and lower eyelid, which bulged from the eyelashes to the infraorbital rim. His upper eyelids were hollow, and the eyebrows were heavy and low set. The tail of the eyebrow had dropped, causing lateral crowding, with two to three deep horizontal creases in the paracanthal area. The patient also had deep frontal wrinkles.

Surgical Plan

Submental liposuction

An extended MACS-lift

Pinch lower blepharoplasty with transconjunctival resection of fat

Short-scar temporal lift with galeopexy (this procedure was done under local anesthesia with intramuscular midazolam 4.5 mg and took 2 hours 40 minutes)

The patient, shown 9 months and 3 years later, demonstrates correction of the cervicomental angle, definition of the mandibular border, and improvement of the jowls, with suspension of the submandibular glands by vertical tightening of the platysma muscles. The nasolabial groove has been reduced, and the midface shows almost complete rejuvenation of the lid-cheek junction. The malar volume is enhanced; this effect can be best appreciated on the oblique view, where the effect of the temporal lift can also be seen. The tail of the eyebrow has been raised about 1 cm. The beard and sideburn remain in an anatomic position.

Today we would add microfat grafting in the midface and nasolabial folds to enhance the long-term stability of this patient's result.

Preoperative

9 months postoperatively

3 years postoperatively

This 56-year-old patient, described earlier (p. 1388), presented with general sagging of the lower part of the face with a marked nasojugal groove and demarcation of the inferior orbital rim, pronounced nasolabial folds, marionette grooves, jowling, and a fatty, infiltrated neck. Correction was performed under local anesthesia with intramuscular midazolam sedation.

Surgical Plan

Extended MACS-lift
Submental liposculpture
Lower pinch blepharoplasty

Her results, seen 18 months postoperatively, reveal a nice redistribution of facial volumes with augmentation of the zygomatic region, shortening of the vertical height of the lower eyelid, reduction of the skeletonized aspect of the orbital region, and a better transition between the lower eyelid skin and the cheek skin. There is visible softening of the nasolabial fold and the marionette grooves, better definition of the jawline, and correction of cervical skin laxity. The patient's general facial shape now appears less square and is more triangular and youthful looking.

This 60-year-old man presented with the stigmata of facial aging in the submental area and a total absence of cervicomental angularity and jawline definition. His jowling, marionette grooves, and nasolabial folds were pronounced. There was general sagging of the midface, with skeletonization of the lower orbital region. Correction was performed with the patient under general anesthesia (his preference), with a 1-day hospital stay.

Surgical Plan

Extended MACS-lift
Submental liposculpture

Transconjunctival fat removal
Pinch lower blepharoplasty

His results, seen 1 year postoperatively, reveal a stable correction of the aging facial features. The cervicomental angle has been reconstructed without opening the neck. Correction of the jowling is evident, with better definition of the jawline. The downward slant of the corners of the mouth was also corrected, and a general triangularization of his square face can be seen on frontal view. Four millimeters of lower eyelid skin was removed in the paracanthal region. This, together with the removal of transconjunctival fat, resulted in a natural, rejuvenated lower eyelid without changing the shape of the palpebral fissure.

In oblique and profile views, the inconspicuous preauricular and temporal hairline scar can be noted as well as the unaltered position of the sideburns because of the purely vertical redraping of the skin. This also resulted in a hair-free tragus, a natural male sideburn, and normal position of beard growth. A short haircut, as usually worn by men, is perfectly possible with the MACS-lift technique.

This 58-year-old patient presented with obvious signs of facial aging after a 60 kg (132-pound) weight loss as a result of a Scopinaro bowel reduction procedure. She showed significant general sagging of the total facial skin envelope, with marked jowling, obvious platysmal bands, and very noticeable perioral rhytids. Surgery was performed with a local anesthetic with intramuscular midazolam sedation.

Surgical Plan

An extended MACS-lift
Submental liposuction

Perioral erbium:YAG laser resurfacing
Posterior cervicoplasty

The 1-year postoperative view shows a very natural correction of the sagging facial features in a cranial direction. Correction of the submental area, with restoration of the cervicomental angle, was accomplished without opening the neck. A posterior cervicoplasty was necessary, not for the effect on the submental area, but for removal of unaesthetic skin folds at the end of the procedure. Jowls and marionette grooves were corrected, as were perioral rhytids. The skeletonized aspect of the orbital region was corrected by upward movement of the malar soft tissues and a subsequent lower pinch blepharoplasty.

Clinical Caveats

A short-scar face lift is not a classic face lift with a short scar.

The only rejuvenating vector is the vertical one. The horizontal vector does not rejuvenate the face, but puts the face under tension and causes flattening of the face.

The vertical vector should work on the deep tissues and on the skin.

Purse-string sutures strongly anchored to the deep temporal fascia are not the same as cable sutures from one point to another. A cable suture gives traction between two points. Purse-string sutures, as used in the MACS-lift, are a facial sculpturing technique that causes multiple microimbrications in the subcutaneous tissue.

After vertical redraping of the skin flap, the skin is resected in the temporal region. This skin resection will act as a lock of the microimbrication result on the subcutaneous facial tissues.

Skin suturing starts from superior to inferior to prevent and treat dog-ear formation in the temporal area.

Only when residual skin folds are visible in the infraauricular region at the end of the skin suturing is a posterior cervicoplasty carried out. This is done only for redraping of unacceptable skin folds and will have no effect on the submental region.

This article started our thinking in the direction of short scars and purse-string suture suspension.

Verpaele A, Tonnard P, Gaia S, et al. The third suture in MACS-lifting: making midface-lifting simple and safe. *J Plast Reconstr Aesthet Surg* 60:1287-1295, 2007.

The minimal access cranial suspension (MACS)-lift exists in a simple and extended version. The simple MACS-lift achieves a vertical lifting of neck and lower half of the face with two purse-string sutures. The action of a third, malar suture gives additional correction of the middle third of the face, and results in the extended MACS-lift. It produces a natural midface lifting through a short scar, with adequate softening of the nasolabial fold and good support of the lower eyelid.

CHAPTER 43

Short-Scar Rhytidectomy

DANIEL C. BAKER

Rhytidectomy is a procedure that continues to evolve as surgeons seek to offer patients natural rejuvenation with reduced morbidity. Over the years I have witnessed an evolution of techniques ranging from basic skin lifts to superficial musculoaponeurotic system (SMAS) procedures to even more complex, deep plane operations in search of an operation that reliably restores facial form with minimal morbidity. More recently, the need for extensive incisions for rhytidectomy has also been questioned. It has become increasingly clear that not all patients require the full classic temporal preauricular and retroauricular incisions. The incisions, as well as the planes or levels of facial dissection, should be individualized for each patient, in keeping with the physical changes related to aging and the desired result. As more patients seek facial rejuvenation at an earlier age, the need for surgical solutions that are less invasive and that involve less downtime is becoming increasingly important.

My approach to rhytidectomy has evolved over time. During my plastic surgery residency in the late 1970s, the rhytidectomy that I was taught was a combination of extensive defatting of the neck with complete platysma muscle transection, plicating the medial borders and pulling laterally. This was presented as the only way to achieve the “best results.” However, after many years of patient complaints, complications, and overoperated necks, I decided to abandon most of these techniques in favor of my current approach—a short-scar rhytidectomy with lateral SMASectomy or SMAS plication in selected cases.

Today there are a variety of rhytidectomy techniques that produce excellent results. Each surgeon must adopt a technique that serves his or her patients well and ideally is safe, consistent, and applicable to a variety of anatomic problems. For me, the short-scar rhytidectomy is a versatile technique that provides the solution I have been seeking for a wide range of problems for patients of various ages, without the downside of more traditional procedures. With this approach I am confident of obtaining consistently good results with shorter scars, minimal risk of complications, reduced morbidity, and speedy postoperative recovery. It is a quick, safe, and reproducible operation that combines the versatility of traditional SMAS flap undermining with the safety and rapidity of SMAS plication or lateral SMASectomy.

Evolution of Technique

SMAS

In 1976 the work of Mitz and Peyronie helped to popularize the SMAS. With this approach, the lateral SMAS was dissected directly overlying the parotid gland. I performed this type of SMAS dissection in the late 1970s and continued to do so into the mid-1980s. Generally I was disappointed with the effects of a simple elevation and tightening of the lateral superficial fascia, because I saw little appreciable difference in overall facial contour, regardless of whether a lateral SMAS dissection had been performed.

Increasing experience with SMAS dissection convinced me that the mobile SMAS anterior to the parotid gland would have to be elevated if the superficial fascia were to effect a change in facial contour. However, this more extensive SMAS dissection places the facial nerve branches in greater jeopardy. Additionally, the superficial fascia tends to thin out as it is dissected more anteriorly, making the SMAS more prone to tears. Because thinning and tearing after SMAS flap elevation was a common occurrence, compounded when significant tension placed on the SMAS flap during suturing resulted in additional tears, I concluded that extensive SMAS dissection was not warranted in most patients and offered little long-term benefit in comparison with SMAS plication.

Lateral SMASectomy

In 1992 I discovered the benefits of the lateral SMASectomy as an alternative to formally elevating the superficial fascia. With this approach, a portion of the SMAS is removed in the region directly overlying the anterior edge of the parotid gland at the interface of fixed and mobile SMAS. Excision of the superficial fascia in this region secures the mobile anterior SMAS to the fixed portion of the superficial fascia overlying the parotid gland. The SMASectomy is performed in a direction parallel to the nasolabial fold to ensure that the vectors of elevation after SMAS closure will lie perpendicular or more vertical to the nasolabial fold, thereby producing improvement in this fold as well as in the jowl and jawline.

Thus lateral SMASectomy became the foundation for my evolving face-lift technique. This was then combined with a short-scar approach, which addressed patient concerns about scarring and morbidity. The lateral SMASectomy also served as a debulking in full faced patients, but in thin faces I continued to perform SMAS plication.

Short-Scar Rhytidectomy

Although most classic face-lift incisions heal well and patients are happy, hairline disruptions like these are deforming and difficult to correct.

The short-scar rhytidectomy with lateral SMASectomy or plication developed out of the demands of younger female patients (mostly in their forties) who sought facial rejuvenation but were adamantly opposed to any scarring behind the ears. These patients objected to the posterior hairline distortion, hypertrophic scars, and hypopigmentation that they often observed in their friends or mothers who had undergone face lifts. They were embarrassed to wear their hair up or in a ponytail with such scars visible.

The concept of mini-lifts or reduced-incision face lifts is not new. Mini-lifts have been performed for almost a century; the first description of such a procedure was by Pas-sot in 1919. These early operations were usually preauricular skin excisions with minimal undermining, resulting in minimal, short-lived improvement. More recently, the S-lift concept and the MACS-lift techniques with suspension sutures have gained popularity.

My first experience with short-scar rhytidectomy was in 1990, when I operated on a young woman who had submental and submandibular fat and early jowling but good cervical skin elasticity. I performed lipoplasty of the neck and jowls with wide subcutaneous undermining in the face, detaching the malar and masseterocutaneous ligaments. A pure skin lift was done, with no retroauricular scars. The result was excellent, and this experience prompted me to adopt this procedure for all of my younger patients with similar anatomic features.

In 1992 I began to incorporate the lateral SMASectomy technique into the face-lift operation for women in their forties. I noticed that vertical elevation of the face had a beneficial effect on the cervical skin. Lax cervical skin was tightened because the soft tissues of the face and neck are linked anatomically. Between 1990 and 1998 I performed this operation, which had no retroauricular scars, on a total of 204 young female patients. The results were “ponytail friendly” for these young, active women.

As I gained experience with this operation and its potential benefits, I extended its application to older patients who demonstrated greater degrees of jowling and cervical laxity. With these patients, more extensive undermining was required in the neck and over the sternomastoid and submandibular regions and usually required a short retroauricular incision. This undermining exposed the platysma muscle in the neck, thereby facilitating elevation at the posterior muscle, continuous with the SMASectomy.

Between 1990 and 2009 I performed more than 2400 short-scar rhytidectomies with lateral SMASectomy or SMAS plication in patients ranging in age from 40 to 74. These patients exhibited a variety of facial aging changes and neck deformities. Today I can safely say that this procedure is as reliable and safe as other face-lift procedures. It is also reproducible by most plastic surgeons with generally consistent results in properly selected patients. However, it is *not applicable to all patients*, particularly those with excessive cervical laxity and poor skin elasticity. As I have gained more experience, my criteria for the best candidates have become more stringent. Today I rarely compromise the result for a shorter scar.

Advantages and Disadvantages

Lateral SMASectomy

Lateral SMASectomy has several advantages over traditional SMAS elevation. Because the procedure does not require traditional SMAS flap elevation, there is less concern about tearing of the superficial fascia. The potential for facial nerve injury is reduced because most of the deep dissection is over the parotid gland. If the SMASectomy is performed anterior to the parotid gland, the deep fascia will similarly provide protection for the facial nerve branches as long as resection of the superficial fascia is done precisely and the deep facial fascia is not violated. Because SMAS flaps have not been elevated, they tend to hold suture fixation more strongly, and thus the potential for postoperative dehiscence and relapse of contour is decreased.

SMAS resection begins over parotid, extends to lateral canthus

Resection at interface of fixed and mobile SMAS

Width of SMAS resection depends on laxity

A lateral SMASectomy or SMAS plication is performed at the interface of the superficial fascia fixed by the retaining ligaments and the more mobile anterior superficial facial fascia.

On closure, this brings the mobile SMAS up to the junction of the fixed SMAS, producing a durable elevation of both superficial fascia and facial fat. In thin-faced individuals, no SMAS or fat is removed; instead, the lax SMAS is imbricated and plicated to recontour atrophic areas in the face and to correct the midface and nasolabial folds.

Short-Scar Face Lift

The primary advantage of a short-scar rhytidectomy is that it allows patients who wear their hair pulled up or back to do so. Any retroauricular scarring or disruption of the posterior hairline makes such patients unhappy. In addition, the operation involves less dissection and is less invasive; presumably this causes less pain and results in a shorter healing time. In patients who develop hematomas, evacuation is easier with less morbidity.

Advantages and Disadvantages of Minimal-Incision Rhytidectomy	
Advantages	Disadvantages
Less dissection	Requires more vertical skin lift
Less invasive	Difficult to fit in “dog-ears” in temporal and earlobe areas
Less scarring	Requires time for temporal hairline scar to smooth
Avoids posterior hairline distortion	Requires time for retroauricular sulcus/earlobe scar to smooth
Allows easier hematoma evacuation	Occasionally causes skin fold at base of earlobe
Neck exposure	Is not applicable to patients with severe cervical laxity and poor skin elasticity
Ponytail friendly	

There are disadvantages as well. This technique is not suitable for all patients, especially those with severe cervical skin laxity. Because the technique requires a significant vertical lift, strict attention must be paid to minimizing temporal hairline shifts. In certain patients an anterior hairline incision must be used. Fitting dog-ears into the temporal and earlobe areas can be a challenge, and these areas take more time to soften and flatten. Exposure of the neck with the short-scar technique is limited, sometimes making the operation technically more difficult.

However, I do not use this technique in every patient, and there is still the occasional patient (usually with a very thin face) who has an excellent result with only a skin undermining and redraping procedure. There are other patients with severe cervico-facial laxity and loss of elasticity who benefit from a classic rhytidectomy operation with retroauricular scars. Most classic rhytidectomy incisions, if well placed and closed without tension, will heal well with minimal scarring.

Preoperative Assessment

Patient Profiles

Based on my surgical experience with this procedure, I have classified candidates for this procedure into four types as follows.

Type I: The Ideal Candidate

Characteristics	Surgical Plan
Age early to late forties	Suction-assisted lipoplasty (neck)
Aging primarily facial	SMASectomy or plication
Early jowling	Plication only in a thin face
Slight cervical skin laxity	Chin implant if indicated
May have submental fat	
May have microgenia	
Good skin elasticity	

Ideal candidates for a short-scar rhytidectomy are usually in their early to late forties, with signs of aging primarily in the face. Although they may have slight cervical laxity, skin elasticity is still good. They have early jowling, often with submental and submandibular fat. Microgenia may also be present.

These patients can be effectively treated with closed lipoplasty of the neck and jowls, wide subcutaneous skin undermining, and lateral SMASectomy or plication. No retroauricular incision is necessary to improve the neck and face. If indicated, a chin implant will enhance the result.

Preoperative: 47 years old

8 months postoperatively

10 years postoperatively: 57 years old

This woman is an example of a type I patient. She underwent a short-scar rhytidectomy and is shown 8 months postoperatively as well as 10 years postoperatively, when she returned for a secondary rhytidectomy.

Preoperative: 47 years old

8 months postoperatively

10 years postoperatively: 57 years old

Scars 10 years postoperatively

This 48-year-old woman had early jowling and cervicofacial laxity. Her face was thin and her body fat was low. At work she always wore her hair in a ponytail and was greatly concerned about retroauricular scars and posterior hairline disruption. Her presentation made her a type I (“ideal”) candidate for short-scar rhytidectomy. Her thin face and hollow cheeks were best treated with plication and imbrication to augment and recontour her face. Her 1-year postoperative results demonstrate an overall change in her facial shape to oval, with correction of the jowls and midface and enhancement of her cheekbones. The lateral view shows correction of the neck, with preservation of the hairline and imperceptible scars.

Type II: The Good Candidate**Characteristics**

Age late forties to late fifties
 Moderate jowls
 Moderate cervical skin laxity
 Submental/submandibular fat
 May have microgenia
 No active platysma bands

Surgical Plan

Suction-assisted lipoplasty (neck)
 SMASectomy/platysma resection
 Plication only in a thin face
 Chin implant if indicated

These patients are usually in their late forties to late fifties with moderate jowling and cervical skin laxity. Submandibular and submental fat is usually present, and they may have microgenia. Medial platysma bands are not present on normal animation. (I do not evaluate the platysma on forced animation or on the basis of static photographs; often what may appear to be significant platysma bands represents laxity only, which can be corrected with a lateral pull.)

Closed lipoplasty of the neck and jowls along with lateral SMASectomy or plication produces a good result in these patients. If indicated, a chin implant will enhance the result. Usually a retroauricular incision is not required. However, if a dog-ear is present at the earlobe, it can be corrected with a short retroauricular incision.

This 55-year-old woman had moderate jowling and cervicofacial laxity with minimal submental fat. Excess skin and fat of the upper and lower eyelids was present. She represented a type II (“good”) candidate for short-scar rhytidectomy. To maintain facial fat and restore facial fullness, plication of the SMAS and platysma was performed. Her 1-year postoperative result demonstrates reestablishment of a youthful, oval facial shape, enhancement of the submalar region and cheekbones, and correction of the oral commissures. The lateral view demonstrates correction of the cervical laxity and jawline, with preservation of the hairline.

Type III: The Fair Candidate

Characteristics	Surgical Plan
Age late fifties, sixties, early seventies	Open submental suction-assisted lipoplasty
Significant jowls	Platysma approximation at hyoid with wedge excision
Moderate cervical skin laxity	SMASectomy or plication
Submental/submandibular fat	Usually extension of incision into retroauricular sulcus
Platysma bands on animation	Chin implant if indicated
May have microgenia	
Some secondary rhytidectomy	

Fair candidates are usually in their late fifties, sixties, or early seventies. They exhibit significant jowling, moderate cervical laxity, and submental and submandibular fat. Significant medial platysma bands, active on natural animation, may also be present.

The approach to type III patients is via an open submental incision connecting subcutaneous undermining with the face and lateral neck. Open lipoplasty of submental and submandibular fat is performed to expose the platysma muscle. A 4 to 5 cm wedge of platysma is removed at the level of the hyoid. The medial borders of the platysma muscle are approximated to define the cervicomental angle. Lateral suturing of the platysma to the mastoid periosteum enhances the jawline. If redundant skin is present at the earlobe after redraping, it can be removed with a short retroauricular incision. It must be emphasized that in a type III patient the neck improvement and its longevity are usually not as successful as when a classic rhytidectomy with retroauricular scars is performed.

This 59-year-old woman had significant jowling and cervicofacial laxity with microgenia. She had excess skin and fat of her upper eyelids and represented a type III (“fair”) candidate for short-scar rhytidectomy. A lateral SMASectomy was performed to reduce jowl and cheek fullness. An upper blepharoplasty was also performed, and a chin implant placed. Her 1-year postoperative results demonstrate improvement in the facial shape and midface, with enhancement of the cheekbones. Neck improvement resulted from midline platysma approximation and a chin implant. No subplatysmal work was done. A rhytidectomy cannot eliminate deep rhytids from the commissures and jowl area.

This 53-year-old woman had always had submental fullness and lacked cervico-mental definition. She represented a type III (“fair”) candidate for short-scar rhytidectomy. Her 1-year postoperative results demonstrate improvement in the neck and jowls and reshaping of the face. Despite the fact that no subplatysmal work was done, the lateral view demonstrates overresection of subcutaneous fat, leaving a slight submental hollow and a prominent, ptotic chin.

Type IV: The Poor Candidate**Characteristics****Surgical Plan**

Age late sixties and seventies	A significant compromise
Significant jowls	Open submental suction-assisted lipoplasty
Poor cervical skin laxity	Platysma approximation at hyoid with wedge excision
Skin folds below cricoid	SMASectomy/platysma resection
Submental/submandibular fat	Removal of dog-ear in retroauricular sulcus
Platysma bands on animation	Chin implant if indicated
Deep cervical creases	Requires more extensive undermining for skin redraping
Poor skin elasticity	Retroauricular incision can always be extended

Poor candidates are usually in their sixties and seventies, with significant jowling and active, lax platysma bands. Skin folds and deep creases below the cricoid cartilage are often present, and cervical skin elasticity is poor. Although these patients are not good candidates for a short-scar rhytidectomy, this operation can be offered to them as a compromise solution that keeps open the option of extending the retroauricular incision if necessary. Laterally and posteriorly, it is usually necessary to undermine over the mastoid and sternocleidomastoid muscles to obtain proper skin redraping. Excess cervical skin must be tailored into the retroauricular sulcus.

The short-scar technique is a compromise in these patients, and the improvement in the neck is rarely as good as would be obtained with a classic rhytidectomy with wide anterior and posterior cervical undermining and redraping.

This 60-year-old woman is an example of a type IV patient. She underwent a short-scar rhytidectomy with a temporal hairline incision. She is shown 1 year postoperatively with no posterior hairline incision.

This 60-year-old woman demonstrated cervical laxity below the cricoid, extending to the sternal notch. She was a poor candidate for a short-scar face lift, which would have compromised the improvement of her cervical laxity. Although the patient has a nice improvement after undergoing a short-scar rhytidectomy, the postoperative result demonstrates persistent cervical laxity extending to the sternal notch. The patient was not happy and required neck revision with a classic retroauricular incision. This much cervical laxity can only be corrected with wide through-and-through undermining and removal of excess skin through the retroauricular occipital incision.

Operative Technique

Anesthesia

In virtually all of the face lifts I perform, the patient is under monitored intravenous propofol sedation. Patients are given oral clonidine, 0.1 to 0.2 mg, 30 minutes before surgery to control their blood pressure. The face and neck are infiltrated with local anesthetic, 0.5% lidocaine with 1:200,000 epinephrine, through a 22-gauge spinal needle. I inject the face before I scrub to provide the requisite 10 minutes for vasoconstriction to occur.

Incisions

When the temporal hairline shift is minimal, the preferred incision is placed well within the temporal hair. With this incision it is often necessary to excise a triangle of skin below the temporal sideburn at the level of the superior root of the helix.

When a larger skin shift is anticipated (frequently the lift is more vertical with a short-scar rhytidectomy) or the distance between the lateral canthus and the temporal hairline is greater than 5 cm, the incision is made a few millimeters within the temporal hairline. Although this is a compromise, the alternative of a receding temporal hair-

line is rarely acceptable to female patients. When the incisions are executed properly (it is essential to bevel the incision at least 45 degrees through the hair follicles as well as the redraped flap so hair can grow through the incision), these scars heal well and are easy to revise or camouflage. The only exception might be in a patient with deeply pigmented skin in whom the scar will contrast and appear as a white line.

The choice of preauricular incision is left to the surgeon. When executed properly, all of these incisions heal well and are imperceptible. I usually prefer a curved incision anterior to the helix and continue inferiorly anterior to the tragus in a natural skinfold. This preserves the thin, pale, hairless tragal skin and its demarcation from the cheek skin, which is usually coarser, thicker, darker, and has lanugo hairs. I perform intratragal incisions in patients in whom the cheek and tragal skin is similar and the tragal cartilage is not sharp or prominent. Closure must be without tension and the flap overlying the tragus defatted to the dermis.

In a short-scar rhytidectomy, I try to end the incision at the base of the earlobe. This is usually possible in type I or II patients, but in type III or IV patients a shorter retroauricular incision is often necessary to correct a dog-ear after the facial flap rotation.

Skin Flap Elevation

All skin flap undermining is carried out under direct visualization with scissors dissection to minimize trauma to the subdermal plexus and preserve a significant layer of subcutaneous fat on the undersurface of the flap. I prefer subcutaneous dissection in the temporal region, because the skin seems to redrape better. I believe that hair loss results primarily from tension rather than superficial undermining. Subcutaneous dissection in the temporal region must be performed carefully to avoid penetrating the superficial temporal fascia that protects the frontal branch of the facial nerve. All dermal attachments between the orbicularis oculi muscle and the skin are separated up to the lateral canthus.

Dissection extends across the zygoma to release the zygomatic ligaments but stops several centimeters short of the nasolabial fold. I have never believed that further dissection provides significant benefits; on the contrary, the only result is increased bleeding. In the cheek, dissection releases the masseteric-cutaneous ligaments and, if necessary, the mandibular ligaments.

Subcutaneous dissection continues over the angle of the mandible and sternocleidomastoid for 5 to 6 cm into the neck. This exposes the posterior half of the platysma muscle. If a submental incision has been made, the facial and lateral neck dissection is connected through and through to the submental dissection.

Defatting the Neck and Jowls

The extent of subcutaneous undermining in the temporal area, cheek, and lateral neck is shown. If excess fat is present, closed or open liposuction superficial to the platysma is performed in the submental and submandibular areas. When necessary, medial platysma approximation is done through the submental incision.

Whenever possible, I prefer closed suction–assisted lipoplasty in the neck and jowls. A 2.4 mm Mercedes-tip cannula is used; it is kept under constant, steady motion in the subcutaneous space. A 3 to 5 mm layer of subcutaneous fat is left on the under-surface of the cervical skin. If the jowls are suctioned, this is always done conserva-

tively. Subplatysmal fat is rarely suctioned or removed, because the facial nerves run just beneath the platysma. Additionally, any patient with significant subplatysmal fat probably has a fat, round face, so removing subplatysmal fat could create an over-operated look. This, of course, is a personal aesthetic surgical judgment.

Lipoplasty is usually performed before elevating the skin flaps, taking care not to oversuction the portion of the SMAS-platysma that will be elevated over the mandible with the lateral SMASectomy.

Open Submental Incision With Medial Platysma Approximation

After many years, I now only open the neck when prominent active platysma bands are present. I have found that I can achieve excellent results with closed lipoplasty and a strong lateral platysma vector. Therefore, in type III and IV patients with active platysma bands on animation, the medial approximation provides another vector to enhance the cervicomental recontouring.

I prefer to make the submental incision in the submental crease. The subcutaneous dissection is performed with the patient's neck hyperextended. Undermining is usually to the level of the thyroid cartilage and the angle of the mandible. Suction-assisted lipoplasty is then performed with a large, single-hole cannula under direct vision. Direct fat excision is carried out, if necessary, but to avoid creating depressions, subplatysma fat is rarely removed.

The medial borders of the platysma muscle are identified and elevated for several centimeters. To break the continuity of the bands, a wedge of muscle is removed at the level of the hyoid bone. The medial borders of the muscle are then sutured together with interrupted buried 3-0 PDS sutures.

The submental incision is left open to allow a final confirmation hemostasis and recontouring after communication with the facial dissection and completion of the lateral SMASectomy.

Lateral SMAS Plication

In the SMAS-platysma resection, the level of resection is superficial to the parotid masseteric fascia that overlies the facial nerve branches. The outline of the SMAS-ectomy is marked on a tangent from the lateral malar eminence to the angle of the mandible, essentially in the region along the anterior edge of the parotid gland. In most patients this involves a line of resection extending from the lateral aspect of the malar eminence toward the tail of the parotid gland. Frequently, orbicularis oculi muscle fibers are exposed at the superior limit of the excision. Usually a 2 to 4 cm segment of superficial fascia is excised, depending on the degree of SMAS-platysma laxity and debulking required.

In a SMAS resection, I like to pick up the superficial fascia in the region of the tail of the parotid gland, extending the resection from inferior to superior in a controlled fashion. When SMAS resection is being performed, it is important to keep the dissection superficial to the deep fascia and avoid dissection into the parotid parenchyma. The size of the parotid gland varies from patient to patient; consequently, the amount of protection needed for the underlying facial nerve branches will also vary. Despite this, as long as the dissection is carried superficial to the deep facial fascia, ensuring that only the superficial fascia is resected, facial nerve injury as well as parotid injury will be prevented. In essence, this is a resection of the superficial fascia in the same plane of dissection in which one would normally raise a SMAS flap.

Vectors

The following vectors are illustrated: (1) vectors of elevation of the SMAS-platysma and (2) vectors of superolateral elevation of the SMAS-platysma and medial approximation of the anterior platysma in the submental area above the hyoid bone. The various vectors accomplish corrections of the anterior neck, cervicomental angle, jowls, and nasolabial folds. The first key suture grasps the platysma at the angle of the mandible and advances it in a posterosuperior direction; it is secured with figure-of-eight 2-0 Maxon sutures to the fixed lateral SMAS overlying the parotid gland. This lifts the cervical platysma and cervical skin, helps to define the jawline, and improves contouring in the submandibular region.

The lines of closure of the lateral SMAS–platysma in the cheek and the lateral neck and medial platysma approximation in the submental area are depicted. Excess fat in the mastoid and submandibular areas is removed by liposuction. After SMAS resection, interrupted 3-0 and 4-0 PDS buried sutures are used to close the SMASectomy; the fixed lateral SMAS is evenly sutured to the more mobile anterior superficial fascia. The last suture lifts the malar fat pad, securing it to the malar fascia. It is important to obtain a secure fixation to prevent postoperative dehiscence and relapse of the facial contour.

If firm monofilament sutures are used, such as PDS or Maxon, the sutures should be buried and the sharp ends on the knot trimmed. Final contouring of any SMAS or fat irregularities along the suture line is completed with scissors. Fat can also be trimmed at the sternomandibular trough; final contouring is accomplished with liposuction.

Skin Closure, Temporal Fascia, and Earlobe Dog-Ears

After SMAS and platysma approximation, some tethering of the skin might appear at the anterior extent of the subcutaneous dissection because of the pull of the underlying SMAS. This can also occur in the lower eyelid with elevation of the malar fat pad. Further subcutaneous undermining is necessary to free these tethers, allowing the skin to redrape.

Facial skin redraping is done with a less-vertical vector than with the SMAS. The first key skin suture rotates the facial flap posteriorly to redrape the midface, jowls, and submandibular skin. Suture fixation is at the level of the insertion of the superior helix. I like to use a buried 3-0 PDS suture through the temporal fascia with a generous bite of dermis on the skin flap. The closure is performed with minimal tension. Staples are used to close any incisions in the hair. A wedge is usually removed at the level of the sideburn to preserve the hairline. If an anterior hairline incision has been made, I like to close it with buried 5-0 Monocryl sutures and 5-0 nylon sutures. Extra time and attention must be spent on this closure to eliminate any dog-ears and obtain the finest scar. Bevelling the facial flap will enhance hair growth through the scar.

Excess skin is then trimmed from the facial flap so that there is no tension on the preauricular closure. Wound edges should be “kissing” without sutures. Trimming at the earlobe must also be without tension, and the skin flap is tucked under the lobe with 4-0 PDS sutures, taking a bite of earlobe dermis, cheek flap dermis, and conchal perichondrium to minimize any tension. A small dog-ear might be present behind the earlobe; this is easily trimmed and tailored into a short incision in the retroauricular sulcus. A closed suction drain is usually brought out through a separate stab wound in the retroauricular sulcus to drain the neck, and a Penrose drain is placed through the temporal incision to drain the face.

This patient underwent a lateral SMASectomy via short-scar rhytidectomy with an anterior hairline incision. She is shown postoperatively at the conclusion of surgery before dermabrasion (A), after dermabrasion (B), in frontal and lateral views 1 week after dermabrasion (C and D), and in a retroauricular view at 2 weeks (E). The bunching around the earlobe will smooth with the passage of time; the retroauricular crease and occipital hairline are undisturbed. The preauricular and temporal hairline inci-

sion is shown 2 weeks postoperatively (*F*). Ancillary procedures included an upper lid blepharoplasty, rasping of the nasal dorsum, insertion of an extended chin implant, perioral and glabellar dermabrasion, and lower lid laser resurfacing.

Complications

The table summarizes the complications of short-scar rhytidectomy in my series, which are consistent with those of other standard face-lift operations. Despite special attention to blood pressure control in the postoperative period, the hematoma rate is still 1.5%. The most common problems are the need for minor revisions of the earlobe and temporal hairline scars, but these are far less significant than when I was revising retroauricular scars or trying to repair posterior hairlines.

Complications of the Short-Scar Face Lift

Complication	Frequency (%)
Hematoma	1.5
Facial paralysis (all resolved in 2 months)	0.3
Infection (abscess)	0.8
Skin slough (minor)	1.0
Hypertrophic scars	2.0
Suture granuloma (PDS)	3.5
Earlobe deformity	0.8
Retroauricular pleating	2.0
Temporal hairline scar revision	3.0
Cervical tightening/platysmaplasty in poorly selected patients	2.0

Outcomes

In properly selected patients, the results and duration seem similar to what is achieved with classic rhytidectomies. Type I and II patients who have returned at 8 to 10 years for secondary lifts were very pleased with the results of the first operation. The short-scar technique was used for all secondary lifts. For type III and IV patients, the result in the neck will not be as good when classic retroauricular incisions are made. This category of patients is more likely to require some type of neck revision. The limitations must be discussed preoperatively.

Of the short-scar rhytidectomies I performed from 1990 to 2009, all but 15 were performed on women. Because a man's neck usually has a thicker layer of skin and muscle, few male patients are candidates for this procedure.

After 20 years and 2400 short-scar rhytidectomies, I implemented stricter indications:

- Young
- Good skin elasticity
- Minimal cervical laxity
- Open neck for platysma
- Rarely compromise the result for a short scar

Results

This 44-year-old woman exhibited the signs of a typical type II patient. She underwent a short-scar rhytidectomy with a SMASectomy and an upper eyelid blepharoplasty. We also inserted a chin implant. She is shown 2½ years postoperatively, with an absence of retroauricular and occipital incision scars.

This 68-year-old woman underwent a short-scar rhytidectomy. A 35% trichloroacetic total facial peel and perioral and glabellar dermabrasion were performed at the time of surgery. A small, extended chin implant was also inserted. This woman was a heavy smoker, so the submental area was not opened. She is shown 5 months post-operatively.

Concluding Thoughts

The short-scar rhytidectomy is an excellent face-lift technique for younger patients with good skin elasticity and minimal cervical laxity. Older patients with excessive cervical laxity and poor skin elasticity do not get optimal results from this technique, so it is a compromise for them. Rarely will I sacrifice the result for a shorter scar.

Clinical Caveats

When the temporal hairline shift is assessed as minimal, the preferred incision is well within the temporal hair.

The temporal hairline incision allows a more vertical elevation of the facial flap while preserving the hairline.

All skin flap undermining is carried out under direct vision (with scissors dissection) to minimize trauma to the subdermal plexus and preserve a significant layer of subcutaneous fat on the undersurface of the flap.

Subcutaneous dissection in the temporal region must be performed carefully to avoid penetrating the superficial temporal fascia that protects the frontal branch of the facial nerve.

Whenever possible, I prefer to use closed section-assisted lipoplasty in the neck and jowls.

I usually perform lipoplasty before elevating the skin flaps. In doing so, I am careful not to oversuction the portion of the SMAS-platysma that will be elevated over the mandible with the lateral SMASectomy.

When SMAS resection is being performed, it is important to keep the dissection superficial to the deep fascia and avoid dissection into the parotid parenchyma. Because the size of the parotid gland varies from patient to patient, the amount of protection for the underlying facial nerve branches will also vary.

After SMAS resection, interrupted 3-0 PDS buried sutures are used to close the SMASectomy, the fixed lateral SMAS being evenly sutured to the more mobile anterior superficial fascia. The last suture lifts the malar fat pad, securing it to the malar fascia. It is important to obtain a secure fixation to prevent postoperative dehiscence and relapse of facial contour.

Annotated Bibliography

Baker DC, Conley J. Avoiding facial nerve injuries in rhytidectomy. *Plast Reconstr Surg* 64:781-795, 1979.

The authors present a detailed anatomy of the muscular branches of the facial nerve and discuss how to prevent injuries to them during rhytidectomy, and how to manage injuries when they do occur.

Connell BF. Contouring the neck in rhytidectomy by lipectomy and a muscle sling. *Plast Reconstr Surg* 61:376-383, 1978.

Accurate diagnosis of the cause of the objectionable contour problems is necessary for the execution of appropriate and adequate surgical technique for correction. The author discusses adequate lipectomy combined with deep support provided by a sling made from full-width platysma muscle flaps for improving neck contour.

Marchac D, Brady JA, Chiou P. Face lifts with hidden scars: the vertical U incision. *Plast Reconstr Surg* 109:2539-2551, 2002.

The authors present their development of a strictly vertical retroauricular incision to minimize visible scarring.

Mitz V, Peyronie M. The superficial musculoaponeurotic system (SMAS) in the parotid and cheek area. *Plast Reconstr Surg* 58:80-88, 1976.

The authors investigated the SMAS in the parotid and cheek areas using anatomic dissections, radiographs, and histologic sections. They reported that the SMAS may be helpful in corrective surgery for facial palsy and during face-lifting operations if a retro-fascial approach is used. This procedure, while safe in the parotid area, can become dangerous in the area anterior to the parotid gland.

CHAPTER 44

Extended SMAS Technique in Facial Rejuvenation

JAMES M. STUZIN

Surgical rejuvenation of the aging face has become one of the most frequently performed surgical procedures in the United States. Face lifting, introduced as a skin tightening procedure in the early 1900s, has technically matured during the past quarter-century. This evolution is directly related to scientific investigation of facial soft tissue anatomy, resulting in a better understanding of the changes that occur with aging. Over the past 30 years, a number of procedures have been developed with a variety of technical approaches to reconstruct aging-related anatomic changes.

When the face lift was first developed, both patients and surgeons focused on the laxity that occurs with facial aging, and efforts were directed to tightening what was loose rather than to restoring the shape of the face—hence the term *face lift* (rather than *facialplasty*), a mechanical term that implies a procedure to lift what has fallen. Unfortunately, this mechanical approach often produced a tight, operated look—the wind-tunnel appearance that has so often been associated with surgical rejuvenation of the aging face. Today, based on a better understanding of facial soft tissue anatomy and the anatomic changes that occur during aging, face lifting has developed into both a reconstructive procedure (to reconstruct the anatomic changes from aging) and a more artistically defined technique that attempts to enhance facial appearance while minimizing any signs that a surgical procedure has been performed.

There are many treatment goals for face lifting other than simply correcting the hallmarks of the aging face, including improvement of the nasolabial folds, jowls, and cervical contour. A face lift must also address the aesthetic concepts of improving shape and bringing out the beauty of the face that existed during youth. The surgeon attempting to meet these goals must have a thorough understanding of facial soft tissue anatomy, the anatomic changes that occur from aging, and the ideal facial shape that can be obtained for a particular patient. The design of the surgical access incisions must minimize scar perceptibility and avoid hairline distortion to prevent surgical stigmata.

Aging in the face is complex and multifactorial, and plastic surgeons may encounter a number of problems during midface rejuvenation, including the following:

- The dermal component of aging related to intrinsic and extrinsic skin changes (dermal elastosis)
- Descent of facial fat
- Facial deflation, which tends to be regionally specific
- Radial expansion as facial fat becomes centrifugally situated away from the facial skeleton

All of these factors influence facial shape with aging. Individual patients exhibit various degrees of all these problems, and each component of the aging face should be addressed according to a patient's specific needs.

Patient photos taken during youth and as the individual has grown older are very helpful in determining how a patient has aged. Youthful photos usually reveal the location of the volumetric highlights present, document areas that have deflated over time, and indicate both the position and vector of facial fat descent. These factors illustrate patient-specific changes in facial shape and clarify the possible methods for repositioning facial fat to improve and restore shape. From my perspective, restoring facial shape is a more worthy aesthetic goal than attempting to tighten a loose face.

Pertinent Anatomy

The anatomy that allows a rhytidectomy to be performed safely is the arrangement of the facial soft tissue in concentric layers. This arrangement allows dissection within one anatomic plane to proceed completely separate from structures lying within another anatomic plane. The layers of the face are the skin; subcutaneous fat; superficial facial fascia (superficial musculoaponeurotic system [SMAS]); mimetic muscles; parotidomasseteric fascia (deep facial fascia); and the plane of the facial nerve, parotid duct, buccal fat pad, and facial artery and vein.

A surgeon attempting to master sub-SMAS dissection must understand the following anatomic components of facial soft tissue anatomy.

ANATOMIC CONSISTENCY Although the thickness of the various layers differ from patient to patient, structures within each layer are anatomically consistent. Considered two-dimensionally, the facial nerve exhibits a variety of branching patterns, but on a three-dimensional basis, the facial nerve always lies within a specific anatomic plane. This arrangement allows the surgeon to perform extensive sub-SMAS dissection safely, as long as the dissection proceeds at a level superficial to the plane of the facial nerve.

SMAS THICKNESS The thickness of the SMAS may vary significantly from patient to patient as well as from one region of the face to another. Overlying the parotid gland, within the temporal region (temporoparietal fascia), and within the scalp (galea), the SMAS is a substantial, discrete layer. As the SMAS is traced anteriorly in the face, overlying the masseter and buccal fat pad and into the malar region, it tends to become thinner and less substantial. Elevating the SMAS in these areas requires precise dissection so the flap is thick enough to be useful in facial contouring.

MUSCLE LAYERS The muscles of facial expression are arranged in four overlapping anatomic layers. The muscles that are encountered during a face lift procedure include the platysma, orbicularis oculi, zygomaticus major and minor, and risorius muscles, which are all superficial mimetic muscles. The deeply situated mimetic muscles are the buccinator and mentalis muscles. Most of the muscles of facial expression lie superficial to the plane of the facial nerve and therefore receive their innervation along their deep surfaces. The only muscles within the facial soft tissue architecture that lie deep to the plane of the facial nerve are the mentalis, buccinator, and levator anguli oris muscles; they receive their innervation along their superficial surfaces.

In this cadaver dissection of the facial nerve, it can be seen that the area directly overlying the zygomatic buttress is devoid of motor branches, and the only nerves in this region are sensory branches. For this reason, dissection in the malar area is quite safe—the malar eminence represents a watershed between the frontal branches of the facial nerve lying superiorly and the zygomatic branches of the facial nerve that lie just inferior to the zygomatic buttress.

Courtesy J.K. Terzis, MD

This cadaver dissection shows the path of the marginal mandibular nerve. The depressor anguli oris muscle has been divided so that the nerve can be seen lying along the deep surface of this muscle. The depressor anguli oris and the depressor inferioris muscles are typical of facial muscles that lie superficial to the plane of the facial nerve and receive their innervation along their deep surfaces.

ANATOMIC FACIAL UNITS The muscles of facial expression that are situated superficially within the facial soft tissue architecture are invested by the superficial fascia. By *invested*, I mean that the superficial fascia lines both the superficial and deep surfaces of these muscles. This SMAS–mimetic muscle complex thus forms a single anatomic and functional unit that moves facial skin during animation.

FACIAL FASCIA Deep to the SMAS–mimetic muscle complex lies the deep facial fascia. The deep facial fascia is a continuation of the superficial layer of the deep cervical fascia cephalad into the face. Where this fascial layer is identified, it is given specific nomenclature. Overlying the parotid gland, the deep fascia is called the *parotid fascia* or *parotid capsule*; overlying the masseter muscle, it is called the *masseteric fascia*; and in the temporal region, it is called the *deep temporal fascia*.

The cadaver dissection on the left is seen after SMAS-platysma elevation within the cheek; the underlying parotid gland, the anterior border of the parotid (marked in ink), and the parotidomasseteric fascia (held in forceps) are exposed. *The significance of the deep facial fascia is that all the facial nerve branches within the cheek lie deep to this layer.* Typically, these nerve branches course deep to the deep fascia until they reach the muscles of facial expression, at which point they penetrate the deep fascia to innervate these mimetic muscles along their deep surfaces. In the cadaver dissection on the right, the parotidomasseteric fascia has been elevated to expose the underlying masseter muscle and the marginal mandibular nerve as it crosses the facial artery and vein.

The essential point regarding the architectural arrangement of the facial soft tissue is that there is a superficial component of the facial soft tissue that is defined by the superficial facial fascia and includes the SMAS and those components that move facial skin (including superficially situated mimetic muscle invested by the SMAS, the subcutaneous fat, and skin). This is in contrast to the deeper component of the facial soft tissue, which is defined by the deep facial fascia and the structures related to the deep fascia, including the relatively fixed structures of the face, such as the parotid gland, masseter muscle, periosteum of the facial bones, and facial nerve branches. As the face ages, many of the typical changes seen are associated with a change in the anatomic relationship between the superficial and deep facial fascia. With age, facial fat descends in the plane between superficial and deep facial fascia, thereby justifying reelevation of fat through sub-SMAS dissection to improve facial shape.

Retaining Ligaments

Communication between the superficial and deep facial fascia occurs at the level of the retaining ligaments. These structures fix facial soft tissue in a normal anatomic position, resisting gravitational forces. Retaining ligaments exist in specific locations of the face, including (1) the malar area, where they are called *zygomatic ligaments*, (2) along the anterior border of the masseter muscle, forming the *masseteric cutaneous ligaments*, (3) over the parotid gland, forming the *parotid cutaneous ligaments*, and (4) in the parasymphysial and symphyseal region of the mandible, where they are called *mandibular ligaments*.

There are two types of retaining ligaments, as defined by their origins. The osteocutaneous ligaments are a series of fibrous bands that run from periosteum to dermis. The zygomatic and mandibular ligaments are examples of these structures.

The second system of supporting ligaments is formed by a coalescence of the superficial and deep facial fascia in certain regions of the face (the parotid-cutaneous ligaments and the masseteric cutaneous ligaments). These fascial connections, which fix both superficial and deep fascia to underlying facial structures, such as the parotid gland and masseter muscle, similarly lend support against gravitational forces through fibrous septa that extend into the dermis. Attenuation of support from the retaining ligaments is responsible for many of the features of facial aging.

In the evolution of midface aging, the zygomatic and masseteric cutaneous ligaments are particularly important. The zygomatic ligaments originate from the periosteum of the malar region as a series of fibrous septa that begin laterally in the region where the zygomatic arch joins the body of the zygoma and permeate the malar pad (fibrous McGregor's patch). A particularly stout ligament originates along the medialmost portion of the zygoma, medial to the zygomaticus minor. The zygomatic ligaments fix the malar pad to the underlying zygomatic eminence in a youthful face.

Attenuation of the zygomatic ligamentous support suspending the malar pad and the medial cheek leads to an inferior migration of these soft tissues adjacent to the line of the muscular fixation of the nasolabial fold. The fold not only deepens with aging, but an accumulation of cheek soft tissue lateral to the nasolabial line also accounts for fold prominence.

Soft tissue support in the medial cheek is provided by a series of fibrous bands that extend along the entire anterior border of the masseter muscle. These fibers, called *masseteric cutaneous ligaments*, are identified superiorly in the malar area, where they mingle with the zygomatic ligaments and extend along the anterior border of the masseter as far inferiorly as the mandibular border. These fibers represent coalescence between the superficial and deep fascia, extending from the masseter muscle vertically to insert into the overlying dermis. When an individual is young, the masseteric ligaments support the soft tissues of the medial cheek superiorly above the mandibular border.

Attenuation of support from the masseteric cutaneous ligament allows the soft tissues of the medial cheek to descend inferiorly, leading to the formation of the facial jowl.

Because of the anatomic relationships of the retaining ligaments, the jowl has constant borders. Anteriorly, the jowl is bordered by the mandibular ligaments. Posteriorly, the jowl complex is positioned along the anterior border of the masseter muscle.

Aesthetic Analysis and Treatment Planning

As the face ages, facial shape changes multifactorially. Some of these changes can be addressed in a straightforward manner, whereas others present difficult technical challenges. A paradox for me has always been that facial anatomy (in terms of basic soft tissue architecture) is essentially unchanged from youth to middle age, but facial appearance changes greatly over time and is patient specific. Although each face ages differently, there are common features in all of them.

Descent of Facial Fat

As the face ages, facial fat descends. As seen in a photograph taken at age 25, this woman has a youthful face full of well-supported facial fat, typically overlying the malar eminence and along the lateral cheek, which overlies the parotid gland and masseter muscle. In addition, there is generally a concavity or depression overlying the buccal recess just anterior to the masseter muscle. The combination of fullness in the malar region and lateral cheek and a concavity overlying the buccal recess accounts for the angular, tapered appearance of the youthful face. In the same woman at age 55, 30 years later, the aesthetic effect of facial fat descent becomes obvious.

Typically, faces in middle age are square, with little differential between malar highlight and midfacial fat. As facial fat becomes more inferior in the face, the face appears visually longer. The aesthetic consequences of loss of facial angularity with aging are as important as the depth of the nasolabial fold and jowling. For me, an improvement of facial shape is one of the primary goals of facial rejuvenation.

Volume Loss and Facial Deflation

Youthful faces are full of well-supported fat. Deflation occurs over time, soft tissue becomes less supported and appears lax, and it tends to be most apparent in areas of the face that have a high density of retaining ligaments (the malar pad, prepatrotid area, lateral and infraorbital rim, and the lateral chin). Youthful faces have a smooth contour between the aesthetic subunits. Middle-aged faces, as a result of both deflation and fat descent, develop lines between the regions. An appropriate aesthetic treatment plan requires repositioning of the descended soft tissue into areas of facial deflation to improve shape, not only to restore the volume of youth, but also to blunt the lines between aesthetic subunits. Volumetric augmentation through autologous fat injection or other injectable soft tissue fillers is an ancillary procedure that can be useful for augmenting areas of deflation.

Deflation is a complex process that tends to be regional and age specific. A breakthrough in understanding how deflation occurs came with a discovery by Rohrich and Pessa. These investigators realized that the subcutaneous fat of the cheek, rather than being homogeneous, is broken into compartments, each with an independent perforator blood supply and surrounded by specific septal membranes. The aesthetic significance of fat compartmentalization is that deflation tends to occur within a specific region of the cheek, rather than deflating homogeneously.

At the risk of oversimplification, one key to understanding facial deflation is the location of the zygomaticus major muscle, which traverses from the malar eminence to the oral commissure. Deflation of the cheek lateral to the zygomaticus major muscle tends to occur independent of deflation in the malar region, medial to the zygomaticus major. For many patients, lateral cheek deflation develops at a younger age than malar pad deflation, and it often appears in patients in their forties.

This 42-year-old patient has early facial aging resulting primarily from deflation. She has a hollowing effect in the lateral cheek and preparotid region. Deflation has occurred in the fat compartments lateral to the zygomaticus major muscle. She is seen before and after a face and neck lift. Anteriorly situated fat was brought into the upper lateral midface, where it filled the areas of deflation, thereby blunting the lines between aesthetic subunits. The change in facial shape is evident; her face appears more structured and supported after facial fat repositioning.

Medial cheek and malar pad deflation tends to occur later in life and is responsible not only for the loss of volumetric support within the anterior cheek, but also for the development of the infraorbital V deformity. Deflation in this region results in an apparent increase in the vertical length of the lower lid as the lid cheek junction visually descends inferiorly into the poorly supported anterior cheek.

An interesting region of deflation develops in some patients in the submalar region lateral to the oral commissure. In these patients, deflation can result in accentuation of the submalar concavity, which can become more obvious after the vertical soft tissue shifts associated with face lifts. An accentuation of the submalar depression lateral to the oral commissure can result in the development of joker lines, or cross-cheek depressions, which may appear in patients who have undergone a face lift. Avoidance of vertical soft tissue repositioning in conjunction with volume addition in the submalar recess lateral to the oral commissure can help prevent the accentuation of postoperative cross-cheek depressions.

This cadaver dissection illustrates the muscular insertions into the oral commissure and modiolus. The small arrow overlies the facial portion of the platysma and points to the risorius muscle; the large arrow points to the depressor anguli oris muscle, where it merges with the platysma. Superiorly, the insertion of the zygomaticus major into the lateral commissure can be seen, with a slip of muscle inserting inferiorly into the modiolus. After deflation in this area, the medial component of the cross-cheek depression develops in the area between the elevator and the depressors of the lip.

Radial Expansion

Not all facial aging is vertical; one major challenge in facial rejuvenation is the radial expansion of facial soft tissue that occurs in the midface. In youth, the skin and underlying subcutaneous fat are densely attached to the deep facial fascia by retinacular fibers running through skin, subcutaneous fat, and superficial fascia that insert into the deep fascia and facial musculature. Over time, with prolonged animation such as smiling, the skin along the nasolabial line is forced deep to the subcutaneous fat, positioned lateral to the nasolabial fold, which attenuates these retinacular attachments. Animation forces the skin and fat lateral to the nasolabial fold to expand radially and prolapse outward from the facial skeleton, accounting for much of the nasolabial fold prominence in an aging face. Radial expansion lateral to the oral commissure and marionette line similarly accounts for the prominence of the jowl in many patients, making older faces appear square and bottom-heavy.

Radial expansion is technically difficult to correct, because there are few surgical solutions for reestablishing the retinacular attachments between skin, subcutaneous fat, and deep fascia. Nevertheless, repositioning facial fat through some form of support to the superficial fascia not only repositions fat vertically, but also provides internal repositioning so that the facial soft tissues lie closer to the facial skeleton. As the soft tissues become situated closer to the underlying deeper structures of the face, facial morphology tends to be restored to a more youthful configuration. Because of the technical difficulty of completely treating radial expansion in many faces, incomplete correction of both the jowl and nasolabial fold is common postoperatively, despite efforts to reposition descended facial fat.

This 59-year-old man lost 41 kg (90 pounds) after a gastric bypass procedure. There are areas of deflation along the infraorbital rim, lateral orbital rim, and malar region. Also noticeable is the apparent length of the lower lid from the infraorbital V deformity in association with malar pad deflation. The radial expansion of skin and fat lateral to the nasolabial fold is most marked on the right side. Not only does the malar fat deflate and descend, but also attenuation of the retinacular connections between skin, fat, and deep facial fascia lateral to the nasolabial line allows centrifugal prolapse of soft tissue, which accentuates the nasolabial prominence. This patient's postoperative results show that the deflated areas have been improved by repositioning fat into them. The nasolabial folds are improved after malar pad repositioning, but the correction is incomplete, especially on the right. Malar pad elevation helps flatten the prominent nasolabial fold and improve the infraorbital V deformity, but it does little to correct radial expansion, with the skin lateral to the nasolabial line remaining prolapsed from its attachments to the facial skeleton.

The Role of Skeletal Support in Formulating a Surgical Treatment Plan

Facial shape and contour are intuitively evaluated when the surgeon analyzes a patient for facial rejuvenation. Often the two-dimensional considerations seen in photographs are the easiest aspects of aging to identify, and factors such as nasolabial fold depth, jowl prominence, and cervical contour become the primary focus for improving the appearance of a middle-aged face. Although these factors are certainly important for treatment planning, the more subtle, three-dimensional qualities of facial shape are equally important and are greatly influenced by underlying skeletal support.

When evaluating facial shape during preoperative analysis, there are several major factors that I have found helpful to consider.

FACIAL WIDTH, BIZYGOMATIC DIAMETER, AND MALAR VOLUME The emphasis of face lifting over the last 20 years has been on malar pad elevation. Although malar pad elevation and restoration of malar highlights is important for improving facial shape, it needs to be patient-specific. Many patients present preoperatively with wide faces, strong malar eminences, and large malar volume with little evidence of malar fat descent. In these individuals it is necessary to evaluate preoperatively the degree of malar pad elevation required to improve facial shape.

Facial width and bizygomatic diameter reflect the underlying degree of skeletal support. Patients who exhibit strong malar eminences and wide bizygomatic diameter often benefit from having malar highlights restored but usually do not require significant enhancement of malar volume, because that causes a wide face to appear even wider postoperatively. Shaping in these faces usually focuses on improving the lower two thirds of the cheek, specifically addressing jowl fat repositioning as well as creating submalar hollowing to improve the aesthetic relationship between malar and submalar regions.

FACIAL LENGTH AND THE RELATIVE VERTICAL HEIGHTS OF THE LOWER AND MIDDLE THIRD OF THE FACE Compared with wide faces, patients who present with vertical maxillary excess often have long, thin faces on the front view. As facial fat descends, it becomes situated anteriorly and inferiorly, making the face appears even longer.

Long, thin faces often benefit from an enhancement of malar volume. SMAS dissection and facial fat repositioning anteriorly over the zygomatic eminence allow the surgeon to restore malar volume, thereby increasing bizygomatic diameter. When malar volume is enhanced, the face appears wider.

CONVEXITY OF THE MALAR REGION JUXTAPOSED WITH THE CONCAVITY OF THE SUBMALAR REGION In youth, facial fat is situated over the malar and prepatid region. Malar fullness is juxtaposed with a concavity in the submalar region overlying the buccinator muscle. As patients age, the relationship between the malar and submalar regions changes, and facial shape changes with it. As facial fat descends and facial deflation occurs, there is less volume overlying the malar eminence, and there is an associated fullness increase in the submalar region. As the aesthetic rela-

tionship between the malar and submalar region changes, there is a loss of the angular, tapered shape of youth, making middle-aged faces often appear oval. With even greater facial fat descent and an increase in submalar fullness, older faces appear square.

Preoperatively, this patient's face is oval as a result of malar deflation. Evaluating the relationship between the malar and submalar regions on the front view, for me, is an essential component of aesthetic treatment planning. For many patients, restoring this relationship by increasing malar highlights and malar volume and reconstructing the concavity in the submalar region becomes a central component of improving facial shape.

Preoperatively, this patient shows a blunting of the relationship between the malar and submalar regions. Postoperatively, enhancing malar volume and the bizygomatic diameter, and restoring the concavity within the submalar region have made her face appear more angular as well as shorter vertically.

The Vertical Height of the Mandibular Ramus and the Horizontal Length of the Mandibular Body

The vertical height of the mandibular ramus and the horizontal length of the mandibular body provide skeletal support for the lower two thirds of the face. Patients who present with a normal mandibular ramus height, as well as adequate horizontal length of the mandibular body, usually have excellent skeletal support for soft tissue repositioning and are, therefore, less of a surgical challenge. Patients with a short mandibular ramus, an open mandibular plane angle, and a short length of the mandibular body typically have poor skeletal support for midface and perioral soft tissue repositioning. These patients are a greater surgical challenge for restoring facial shape, and they often benefit from volumetric augmentation, either alloplastic or autogenous, to enhance skeletal support.

Differential Vectors for Redraping SMAS Dissection and Skin Flap

Dermal elastosis and skin laxity in an aging face often do not occur in the same direction nor at the same rate as the descent of fat and other factors affecting the superficial fascia. The main advantages of performing skin dissection separate from SMAS dissection is that it allows these two layers to be draped along vectors that are independent of one another. Another advantage of a two-layer SMAS face lift is that the contouring tension is placed on the superficial fascia, thereby allowing the surgeon to use less tension for skin closure. This also improves control over scar perceptibility. In my experience, facial fat is usually repositioned in a more vertical vec-

tor than skin flap redraping. Strong vertical shifting of the cervicofacial flap is traditional in many face lift techniques. Although skin tightening can produce a dramatic improvement in facial laxity, the aesthetic effects of vertical skin vectoring unfortunately have been poorly defined. Specifically, when skin is shifted in a cephalad direction, the effect of skin tension commonly produces an accentuation of flatness in the prepatotid region, an area that typically deflates with aging. In my opinion, vertical skin shifting often produces an unnatural tightness, producing the typical effects associated with rhytidectomy. If the surgeon has been successful in repositioning descended facial fat, strong vertical skin tension is neither desirable nor required to enhance the postoperative result.

These two patients show the effect of vertical rotation of the cervicofacial flap associated with hairline distortion. A skin flap that is overrotated in a cephalad direction not only can compromise the temporal hairline, but also tends to produce flatness in the lateral midface overlying the masseter and parotid. This imparts a tight, unnatural appearance to the face. The effects of scar perceptibility is evident when strong skin tension is used in an attempt to contour the face.

Surgical Technique: Extended SMAS Dissection

Most patients who have enough laxity to justify a face lift will benefit from tightening the superficial fascial layer. Restoring support to the underlying deeper facial soft tissues has become a key part of my approach to improve facial aging. If the SMAS is thin and tenuous, plication of this layer is an alternative to formal SMAS elevation. However, in my opinion, better contouring and longer-lasting results are obtained after a formal dissection of the superficial fascia.

In skin flap dissection, it is important to develop uniform skin flaps during the subcutaneous undermining, taking care to leave some intact fat along the superficial sur-

44-1 Face lift with
extended SMAS
Vicryl mesh fixation

face of the SMAS, especially where the SMAS is to be dissected. If the skin flaps are dissected so that no fat is left along the superficial surface of the SMAS, then the SMAS becomes more difficult to raise, being thin, tenuous, and prone to tearing. In a SMAS-type face lift, much of the contouring is obtained by elevation and fixation of the SMAS layer. The more substantial the SMAS flap, the better long-term results that can be obtained.

I carry the subcutaneous skin flap dissection well into the malar region and usually undermine the skin overlying the lateral two thirds of the zygomatic eminence. I prefer to stop undermining the skin several centimeters lateral to the nasolabial fold, because this preserves some of the attachments that go from SMAS to the facial skin. The preservation of these attachments, followed by adequate undermining of the SMAS, allows the surgeon to reelevate anteriorly displaced fat and skin through SMAS rotation rather than by redraping the superficial fascia completely independent of skin flap redraping. In my opinion, this maneuver produces a more pleasing aesthetic result in most patients and preserves some of the peripheral vascularity to the facial skin flap.

SMAS Elevation

The dissection of the superficial fascia allows the surgeon to reelevate the jowl and descended malar fat upward into the face. In patients with prominent nasolabial folds and significant extraorbital hollowing, the SMAS dissection should extend into the malar region to reelevate the malar fat pad over the zygomatic eminence. An added benefit of performing a more extensive anterior dissection of the SMAS is that it frees this layer from the restraint of both the zygomatic and masseteric ligaments, and this anterior release provides for a more complete elevation of the facial fat below the oral commissure and along the anterior portion of the jowl.

The incision design for the extended SMAS dissection is an extension of a standard lateral SMAS dissection. The malar aspect of the dissection allows for the repositioning of facial fat along the infraorbital and lateral orbital rim, as well as restoring malar volume. The SMAS dissection just lateral to the zygomatic eminence provides access to the masseteric ligaments to allow jowl fat elevation and restoring submalar concavity. The dissection laterally in the cheek frees the SMAS from the parotid, providing for repositioning descended platysma, thereby improving mandibular border contour.

The incisions for extended SMAS dissection begin approximately 1 cm inferior to the zygomatic arch to ensure that the frontal branch of the facial nerve is preserved. This horizontal incision is continued several centimeters forward to the region where the zygomatic arch joins the body of the zygoma. At this point, the malar extension of the SMAS dissection begins with the incision angling superiorly over the malar eminence toward the lateral canthus for a distance of 3 to 4 cm. On reaching the edge of the subcutaneous skin flap in the region of the lateral orbit, the incision is carried inferiorly at a 90-degree angle toward the superior aspect of the nasolabial fold. A vertical incision is designed along the preauricular region, extending along the posterior border of the platysma to a point 5 to 6 cm below the mandibular border. In essence, the malar extension of the SMAS dissection simply represents an extension of a standard SMAS dissection into the malar region in an attempt to obtain a more complete form of deep layer support.

To obtain mobility of the superficial fascia in an extended SMAS dissection, the surgeon must mobilize the SMAS peripheral to the restraint of the retaining ligaments. To ensure adequate flap mobility, the SMAS needs to be completely dissected from the underlying parotid gland and from the superior aspect of the masseteric ligaments and the zygomatic ligaments.

The SMAS in the malar region is then elevated in continuity with the SMAS of the cheek. When elevating this flap, the fibers of the orbicularis oculi, as well as the zygomaticus major and minor, are usually evident and the flap is elevated directly along

the superficial surface of these muscles. It is important to carry the dissection directly external to these muscle fibers, where a natural plane exists, remembering that the facial nerve branches lie deep to these muscular bellies. The malar SMAS is elevated until the flap is freed from the underlying zygomatic prominence.

Completely freeing the SMAS from the zygomatic attachments is an important technical point in obtaining the mobility necessary to reposition the malar soft tissue superiorly. To obtain this mobility usually requires a division of the upper fibers of the masseteric cutaneous ligaments, which will expose the underlying body of the buccal fat pad. The cheek portion of the SMAS dissection is performed beginning directly overlying the parotid gland and then extending this dissection anterior to the parotid utilizing a combination of sharp and blunt dissection toward the anterior border of the masseter.

It is often necessary to extend the malar SMAS dissection more peripherally than the subcutaneous dissection to obtain adequate flap mobility of the soft tissues lateral to the nasolabial fold. This portion of the dissection is easily performed by simply inserting the scissors in the plane between the superficial surface of the elevators of the upper lip and the overlying subcutaneous fat. Once the scissors are inserted in the proper plane, the surgeon bluntly dissects in a series of passes toward the nasolabial fold (*green area*). *The scissors must remain superficial to the elevators of the upper lip to prevent motor nerve injury.* Usually three or four passes are required to obtain adequate flap mobility.

In most patients, after extended SMAS dissection of the cheek and malar regions, mobility of the soft tissues lying lateral to the nasolabial fold remains restricted unless the dissection is carried more medially. This restriction in movement results from the undivided retaining ligaments that originate medial to the zygomaticus minor. To improve mobility, I commonly continue malar pad elevation medially in an area where I have not subcutaneously undermined the skin. This dissection is carried directly in the plane between the malar fat and the superficial surface of the elevators of the upper lip. It is usually quite easy to delineate this level of dissection after the malar SMAS elevation is complete, and the superficial surface of the elevators of the upper lip visualized. The scissors are then inserted directly superficial to the elevators of the upper lip, and blunt dissection is quickly performed by pushing the scissors in a series of passes bluntly toward the nasolabial fold. I find that when we insert the scissors in the proper plane, the dissection quickly glides through the malar soft tissues, and I usually feel a “snap” as we dissect through the remaining retaining ligaments. Once these structures are divided, greater mobility can be felt when traction is applied to the malar portion of the SMAS flap, translating into greater movement along the uppermost portion of the nasolabial fold.

Repositioning and closure of the SMAS is then performed. The malar SMAS flap is advanced superolaterally over the zygomatic prominence in a direction perpendicular to the nasolabial fold, and usually paralleling the zygomaticus major muscle. After superior and lateral advancement, if a malar augmentation is not planned, the excess tissue can be excised and the flap securely fixated to the zygomatic periosteum with interrupted sutures.

Once the malar flap is secure, the cheek-SMAS flap is rotated superiorly perpendicular to the mandibular border. This portion of the SMAS flap is used to contour jawline and jowl. The SMAS overlying the preauricular region and ear is then treated as a transposition flap and carried posteriorly behind the ear, helping to restore tone to the submental region and neck. After trimming, the SMAS flap is carefully secured with multiple interrupted sutures. Occasionally skin dimpling is noted after securing the SMAS flap; this results from the forces of SMAS rotation on resuspended facial skin. Skin dimpling is treated by simply performing a bit more subcutaneous undermining before skin flap redraping.

That the SMAS has been adequately mobilized can be determined by observing the effect of facial contouring when traction on the SMAS is applied. In general, freeing the SMAS past the restraint of the retaining ligaments provides the mobility necessary to obtain consistent facial contouring through SMAS redraping.

After proper contouring of the SMAS dissection, the facial skin flaps are rotated and closed in the direction decided on based on preoperative evaluation. In general, these skin flaps are inset with a minimum degree of tension placed along the key sutures and then the skin flaps are trimmed with a degree of redundancy between the key sutures to minimize tension along the incision sites. I favor restoring contour face lifting through deep layer support, placing the tension on the SMAS and platysma closure, and minimizing the tension on skin flap closure to obtain consistency in terms of scar perceptibility. Stated in other terms, facial contouring is restored through deep layer support rather than through tension in skin flap redraping.

To summarize, the key points in mobilizing the superficial fascia from the restraint of the retaining ligaments of the cheek are as follows:

The SMAS overlying the parotid gland and malar eminence tends to be substantial and easy to dissect, with both the parotid and zygomaticus major and minor muscles protecting the underlying facial nerve branches. These areas are very safe regions to begin SMAS elevation and delineate the sub-SMAS plane. The thinnest fascial component of an extended SMAS dissection is in the region just lateral to the zygomaticus major muscle, where the SMAS splits to invest the elevators of the upper lip. Dissecting the skin flap thinly in this region leaves a substantial amount of subcutaneous fat intact along the surface of the superficial fascia, providing greater ease in SMAS dissection and minimizing the possibility of tearing this layer.

The most difficult portion of an extended SMAS dissection is freeing the superficial fascia from the restraint of the superior masseteric ligaments, which are lateral to the zygomaticus major muscle. If these ligaments are not mobilized, restricted movement is noted in the portion of superficial fascia that affects contouring along the lower nasolabial fold, oral commissure, and anterior jowl. The zygomatic branches of the facial nerve are in close proximity to the upper masseteric ligament. At times it can prove difficult to differentiate between ligaments and facial nerve branches. Caution is essential in this region of dissection.

Variations in Extended SMAS Technique to Effect a Restoration in Facial Shape

The biomechanics of SMAS repositioning have been previously described and are influenced by the degree of release, vector of fat repositioning and how the superficial fascia is fixated. As postoperative contour is dependent on each of these factors, preoperative planning needs to be patient specific in terms of the degree of SMAS release required, the vectors in which facial fat is repositioned, and the location and method for SMAS fixation.

Release

The incision design of an extended SMAS dissection allows for complete release of the SMAS from its underlying retaining ligamentous attachment in the lateral midface. As surgeons, there is a tendency to believe that a greater degree of SMAS dissection equates with a better result, but this has not been my experience. Rather, precision in the degree of SMAS dissection and its release from the retaining ligaments as dictated by the aesthetic needs of a patient increases surgical control and consistency in while minimizing morbidity.

How much to release the SMAS, and how high and anterior to carry the SMAS dissection, needs to be decided preoperatively. In patients who present with adequate malar volume, wide bizygomatic diameter and little evidence of malar pad descent, it is usually unnecessary to carry the SMAS dissection medial to the lateral orbital rim (although I usually carry the dissection high within the malar eminence to allow fat repositioning along the infraorbital and lateral orbital rims). Most commonly, these types of patients require only a restoration of malar highlight and not significant anterior malar volume enhancement. Limiting the SMAS dissection to the lateral aspect of the malar eminence will not increase facial width on the front view. Typically, the shaping considerations for these patients is focused on reducing fullness in the submalar region. Sub-SMAS dissection along the lateral aspect of the zygomatic eminence provides exposure to the juxtaposed masseteric ligaments, allowing the submalar fat to be repositioned superiorly along the concavity of the underlying buccinator, thereby restoring submalar hollowing.

Long faces often benefit from carrying the malar portion of the extended SMAS dissection anteriorly, medial to the lateral orbital rim so that malar volume restoration is performed along the anterior aspect of the zygomatic eminence. Carrying the SMAS dissection more medially allows the surgeon to enhance malar volume and restore malar highlights anteriorly over the zygomatic eminence, thereby increasing facial width on the front view.

Patients with wide bizygomatic diameters and good underlying skeletal support typically do not require a significant anterior malar dissection to improve facial shape. Most commonly, the SMAS dissection in these patients, while kept high, is extended only as medial as the lateral orbital rim, so that malar volume restoration is limited to the lateral aspect of the zygomatic eminence. The shaping considerations for these types of faces usually emphasize reducing fullness within the submalar area, as well as jowl fat elevation. Postoperatively, the patient's face appears more tapered and thinner in morphology through facial fat repositioning without removal of facial fat.

Vectors of Fat Elevation: Facial Asymmetry

All patients exhibit some degree of facial asymmetry. Commonly, one side of the face is vertically longer, and the short side of the face is usually wider than the long side. Malar highlights are typically more superiorly located on the long side of the face and, with age, facial fat tends to descend in a more vertical direction on the long side. As facial asymmetry and facial skeletal configuration are asymmetric in most individuals, it follows that the vectors of fat elevation (SMAS repositioning) should be specific for the right and the left side of the face.

The vector in which the SMAS is repositioned has a significant impact on the location and volume of elevated facial fat, thereby influencing facial shape. Decisions regarding the direction of SMAS vectoring for the right and left side of the face are best determined preoperatively, as it is very difficult to make aesthetic vector judgments intraoperatively with the patient recumbent.

SMAS vectors influence postoperative facial shape. Vertical SMAS repositioning typically provides a larger amount of fat for enhancing the malar eminence, as well as allowing for a reduction in fullness within the submalar region as fat is forced vertically along the concavity of the buccinator. For this reason, vertical SMAS vectors are often indicated to reshape round, full faces, allowing them to appear more tapered and thinner postoperatively. In this patient, a small amount of jowl defatting through needle aspiration was also performed.

If the SMAS is vectored more obliquely, there is less volume of fat brought into the malar region and a greater volume of fat repositioned into the submalar region. Oblique SMAS repositioning is therefore helpful in elderly patients who appear gaunt over the buccal recess, as it allows the surgeon to volumetrically enhance the submalar region.

This patient exhibited asymmetry in the submalar region preoperatively. The area appeared hollow and concave on the right and fuller on the left side. For this reason, the SMAS was vectored obliquely on the right to volumetrically enhance the submalar region; it was vertically vectored on the left to restore submalar hollowing and balance the two sides of her face.

SMAS Fixation

In a two-layer SMAS-type face lift, the tension of contouring is placed on the superficial fascia rather than on the skin envelope. Thus the fascial quality and tensile strength of the superficial fascia has an influence on both the longevity of result and the volume of fat, which can be repositioned intraoperatively and maintained postoperatively. In other words, soft tissue quality influences long-term contour and is the primary reason that face lifts in young patients are more predictable.

In an effort to improve fascial quality in a SMAS face lift, for over a decade I incorporated Vicryl mesh into the SMAS fixation. It was my initial observation that incorporating Vicryl mesh into fixation improved not only longevity of result, but also provided greater aesthetic control. However, for the past 2 years I have stopped using Vicryl mesh, because I have come to realize that the predominant factor in improving fixation is the method in which the superficial fascia is secured. Obtaining a secure fixation using multiple sutures placed deep within the superficial fascia allows the surgeon greater control in postoperative shape. Suturing the SMAS under moderate tension affects facial shape:

Adding more sutures allows the surgeon to stack volume in specific areas of the midface, which is useful in augmenting areas of deflation, as well as augmenting volume along the malar eminence.

As the superficial fascia is sutured under tension, facial fat is not only repositioned vertically, but also repositioned internally, forcing the soft tissue to conform to the underlying deep facial structures. This gives the surgeon greater control in improving radial expansion.

The excess SMAS, rather than being excised, is rolled onto itself to form a double layer of SMAS thickness. It is then fixated to the periosteum of the zygomatic eminence. An added benefit of preserving the excess SMAS rather than excising it is that as the thickened SMAS layer is secured to the zygomatic eminence, it highlights the malar region, serving as an autogenous malar augmentation. Highlighting the malar area tends to enhance angularity in facial contour.

Correction of Platysma Bands and Cervical Obliquity

The best approach to the anterior platysma is through a submental incision, placed just caudal to the submental skin crease. If this crease is very deep, the skin cephalad is elevated toward the base of the chin pad and along the caudal mandibular border to free any retaining mandibular ligaments, which tend to accentuate the crease. After this, the cervical skin is carefully elevated. The cervical skin is usually undermined at least to the level of the cricoid.

When the platysma muscle is exposed anteriorly, most patients exhibit a decussation of platysmal fibers across the midline, at least for a few centimeters below the mentum. If platysma band surgery is planned, these decussating fibers must be sharply divided with scissor dissection directly in the midline. Then the medial edge of the platysma is mobilized from the mentum inferiorly at least to the hyoid and commonly as caudal as the cricoid cartilage. Mobilization, usually performed using a combination of sharp and blunt dissection, separates the platysma from the underlying subplatysmal fat, the anterior belly of the digastric muscle, and the strap muscles overlying the thyroid cartilage. At times numerous small venules are encountered within the subplatysmal fat and careful hemostasis must be obtained. After mobilization of the medial edges of the platysma, the subplatysmal fat is conservatively contoured according to preoperative planning.

Following mobilization, the medial edge of the platysma muscle is grasped on either side and overlapped in the midline to estimate the amount of excess muscle present. Muscle excess varies from patient to patient. A portion of the medial edge can be excised to remove redundancy within the platysma. A conservative resection is performed to avoid undue tension at the time of suture plication.

Muscular plication consists of edge-to-edge approximation using multiple interrupted sutures at the mentum and extending at least to the level of the hyoid. This longer plication enhances the surgeon's ability to tighten and contour the platysma so that it adheres to the floor of the mouth and the thyroid cartilage. This produces a better foundation for redraping of cervical skin. Suture placement back from the leading edge of the muscle, in areas of intact muscular fascia, is an important technical point in preventing suture pull-through postoperatively.

In most patients, the edge-to-edge suturing below the hyoid is continued inferiorly toward the cricoid cartilage. A low plication joining a widely separated platysma over a prominent thyroid cartilage tends to blunt a prominent larynx and produce a rounder, more feminine appearance to the neck.

After edge-to-edge approximation of the platysma, some form of muscular release is performed. This muscular release commonly involves a partial transection of the platysma muscle, with the myotomy performed inferiorly within the neck. This usually consists of a horizontal cut extending from the midline to the anterior border of the sternocleidomastoid muscle.

Platysma transection is an effective technique for treating platysma bands and obtaining the desired cervical contour. This procedure must be performed meticulously. Early experience with transection was fraught with complications; specifically, if the transection was performed at a high level, it could cause unveiling of the submaxillary glands and denervation of the platysma, leading to lower lip dysfunction. Also, obvious contour depressions associated with divided muscular edges could occur in an overly thin neck.

The key to platysma transection is that the transection of the muscle must be performed lower in the neck, often as inferior as the level of the cricoid cartilage. The disadvantage of horizontal transection at this level is that a depression in the neck can develop if preplatysmal fat has been removed at the level at which the transection is performed. Preservation of preplatysmal fat lower in the neck where the transection is to be performed is obviously an important factor in preventing this problem.

In most patients, only partial division is required. The myotomy is performed from the midline laterally until the tension is completely released from the platysmaplasty closure (approximately the anterior border of the sternocleidomastoid muscle in most patients).

The muscular release seen after platysma transection serves many purposes:

- It alleviates tension along the medial portion of the platysma transection following plication.

- It allows the platysma to shift superiorly, producing a deeper cervicomental angle.

- It prevents the conversion of two platysmal bands to a single band after edge-to-edge approximation, which can be visible when the neck is extended.

Sequence of SMAS Fixation Versus Platysmaplasty

Because the SMAS and the platysma lie in the same anatomic layer, if platysmaplasty is performed before the SMAS dissection, it can adversely affect facial contour. Contouring the neck before the midface can also present problems. When the platysmaplasty is performed first, the descended jowl fat is locked down into the neck, and movement of the superficial fascia diminishes after elevation of the SMAS. This diminished movement tends to lessen the surgeon's ability to modify facial shape; it also produces a less aesthetic contour. If the SMAS dissection is performed before the platysmaplasty, descended jowl fat is brought cephalad to the mandibular border and is easily repositioned. After the SMAS has been securely sutured bilaterally, the mandibular border appears more distinct, making cervical contouring less demanding. When performing platysmaplasty subsequent to SMAS fixation, the surgeon will notice less redundancy along the medial borders of the platysma; there is also less need to resect muscle at the time of platysmaplasty. The enhanced contour effects of extended SMAS dissection, associated with precise platysmaplasty, tend to diminish the need to remove cervical fat. In general, the neck and jawline appear softer if preplatysmal fat is preserved when contouring the neck.

This patient illustrates how facial fat reelevation influences cervical appearance. Sequencing errors can lead to loss of contour; I prefer to perform SMAS elevation and fixation before performing platysmaplasty. As the facial fat and skin are reelevated upward into the midface through SMAS rotation, the mandibular border becomes more distinct, making cervical contouring more predictable.

This woman demonstrates the result after extended SMAS repositioning and platysmaplasty.

This patient is shown before and after an extended SMAS dissection. By reelevating descended facial fat back up toward the malar region and lateral midface and securing it there intraoperatively, her facial shape is improved. The mandibular border has been enhanced through SMAS repositioning and platysmaplasty.

Incisions

The importance of incision quality cannot be overemphasized in diminishing signs that the patient has undergone a surgical procedure. One of the major advantages of a two-layer face lift is that the tension of contouring is along the superficial fascia, and thus there is less need to redrape the skin flap with great force. Decreased tension on the key sutures in both the preauricular and postauricular region provides greater control over scar perceptibility. If the incisions are artistically designed, patients can typically wear their hair up off their ears without the obvious stigma that a face lift has been performed.

Many authors have described the salient factors regarding incision design, these main points should be emphasized:

Tragal incisions, placed at the margin of the tragus rather than preauricularly, are preferable, because the color difference between the pale skin of the ear and the blush skin of the cheek is usually better camouflaged when the incision is brought internally into the ear.

Tragal incisions are more demanding than preauricular incisions, requiring precise design and placement so that the tragus is not distorted. The aesthetic unit of the tragus is rectangular, as opposed to semilunar. If the surgeon designs the tragal incision properly, respecting the incisura of the tragus, the tragus will appear normal in its shape postoperatively, exhibiting both a visual beginning at its junction with the helix and a visual ending along the preserved incisura.

Detached earlobes tend to appear more natural than attached earlobes. If a small cuff of cheek skin is left attached to the earlobe, it will allow surgical rotation of the skin up under the earlobe during skin flap redraping, with suturing of the earlobe distinct from the cheek flap. The earlobe should be inset in an axis posterior to the axis of the pinna, thereby avoiding a pixie deformity.

This intraoperative photograph illustrates the standard tragal incision with preservation of the incisura of the tragus. The incision is carried around the earlobe approximately 1 to 2 mm caudal to the junction of the earlobe with the cheek skin.

Left: A preauricular incision is shown 2 months postoperatively. Again, the problem with preauricular incisions is that the difference in color between the skin of the cheek and the skin of the ear is more visible in this anterior incision location. *Center:* A tragal incision is seen 5 months postoperatively; this incision was patterned after the

methods described in the preceding figure. *Right:* A well-designed and inset tragal incision should produce an imperceptible, normal-appearing tragus that exhibits both a visual beginning and end and a detached-appearing earlobe.

There is an increasing public demand for facial rejuvenation at earlier ages, when facial laxity is often minimal. This places the onus on the surgeon to create incisions that are imperceptible if these procedures are to be justified. No matter how well deep-layer support is obtained and facial contour improved by SMAS elevation and platysmaplasty, if the incision is obvious, scar quality poor, the hairline disturbed, or the earlobe deformed, the overall result will be disappointing.

Concluding Thoughts

From a personal perspective, after close to two decades of striving to improve techniques in facial rejuvenation, it is my firm conviction that improving technical control when contouring the superficial facial fascia and platysma provides a more consistent, aesthetically pleasing result that is nonsurgical in appearance. To perform a successful two-layer SMAS-type face lift, the surgeon must not only understand facial soft tissue anatomy, but also must perform a procedure that demands technical precision. A two-layer SMAS-type face lift is a time-consuming operation, with both the skin flap elevation and the dissection of the SMAS requiring meticulous, accurate dissection. Obtaining consistency with this procedure is challenging because of the variability among individuals in the thickness of subcutaneous fat and the SMAS. After precise dissection, secure fixation of both the SMAS and platysma is essential to maintain the desired postoperative contour. Ensuring meticulous hemostasis, followed by careful skin flap inset, are required to minimize postoperative scar perceptibility and ensure a rapid postoperative recovery.

Despite these demands, I have found the extended SMAS technique to be rewarding, with a high degree of patient satisfaction. All techniques have advantages and disadvantages. For me, the biggest advantage of the extended SMAS technique remains its aesthetic versatility, allowing the surgeon to vary the contouring aspects of the procedure according to the aesthetic needs of the patient.

Clinical Caveats

Patient selection is probably the most critical factor when determining the success of a proposed aesthetic procedure.

The anatomic arrangement of the facial soft tissues as a series of concentric layers is key to the safety of rhytidectomy procedures. This concentric arrangement allows dissection within one anatomic plane to proceed completely independent of structures lying within another anatomic plane.

Improving technical control when contouring the superficial facial fascia and platysma provides a more consistent, aesthetically pleasing, nonsurgical-looking result.

The surgical significance of the deep facial fascia is that all the facial nerve branches within the cheek lie deep to the deep facial fascia.

Although aging is a complex process, many of the stigmata developing in the aging face involve a change in the relationship between the superficial and deep facial fascia, with the superficial unit of the facial soft tissue descending inferiorly in relation to the fixed deeper structures of the face.

The importance of the zygomatic ligaments lies in their ability to suspend malar soft tissue superiorly over the zygomatic eminence. With aging, malar support commonly attenuates, leading to an inferior migration of malar soft tissue. Attenuation of support from retaining ligaments, dermal elastosis, and facial lipodystrophy are the three main components that must be addressed to reconstruct the anatomic changes resulting from aging.

The principal advantage of performing skin undermining separately from SMAS dissection is that it allows these two layers to be redraped along vectors that are independent of one another.

The significance of the retaining ligaments is their location, which determines the degree of surgical dissection necessary in face lifting.

In face lifting, it would seem that wide mobilization and aggressive dissection would improve contour, but my experience with wide dissection has led me to a contrary view. I have found that wide dissection peripheral to the restraint of the retaining ligaments to be counterproductive in an extended SMAS face-lift technique.

Rhytidectomy can be considered a reconstructive procedure in that facial soft tissue anatomy is restored to a state resembling its structure before the degenerative effects of aging occurred.

More than any other factors, skin quality and elasticity have perhaps the greatest influence on outcome after a rhytidectomy.

Buccal fat removal tends to reduce facial fullness, but rarely does it improve prominent jowls.

In most patients, jowling can be improved through SMAS rotation.

The prominent nasolabial fold requires restoration of malar support to produce a lasting change in contour. In my experience, extending the cheek SMAS dissection into the malar region to restore malar support has been helpful in improving prominent nasolabial folds.

Correction of the obtuse neck involves restoration of skin tone, contouring of regional lipodystrophy, and restoration of platysma support.

One of the major advantages of a two-layer face lift is that the tension of contouring is along the superficial fascia, and thus there is less need to redrape the skin flap with great force.

The importance of incision quality cannot be overemphasized in diminishing the signs that the patient has undergone a surgical procedure.

The postauricular incision extends along the postauricular groove, not up onto the conchal surface.

Because the SMAS and platysma represent the same anatomic layer, if platysmoplasty is performed before the SMAS dissection, it can adversely affect facial contour. Contouring the neck before the midface can also present problems.

In skin flap dissection, it is important to develop uniform skin flaps during the subcutaneous undermining, taking care to leave some fat intact along the superficial surface of the SMAS, especially in the regions where the SMAS is to be dissected.

The SMAS overlying the parotid gland and malar eminence tends to be substantial and easy to dissect, with both the parotid and zygomaticus major and minor muscles protecting the underlying facial nerve branches. These areas are very safe regions to begin SMAS elevation and delineate the sub-SMAS plane.

Because the SMAS and platysma are in the same layer, what the surgeon does in the face influences the contour in the neck.

Annotated Bibliography

Feldman JJ. Neck Lift. St Louis: Quality Medical Publishing, 2006.

Corset platysmaplasty is useful for all patients with visible paramedian muscle bands and all patients who would benefit from having a decussated upper neck platysma opened for submuscular defatting, including patients with oblique, palpably firm necks that suggest a vertically short platysma muscle or low-lying hyoid bone.

Mendelson BC. Correction of the nasolabial fold: extended SMAS dissection with periosteal fixation. *Plast Reconstr Surg* 89:822-833; discussion 834-835, 1992.

The nasolabial fold has defied satisfactory correction with the face-lift operation despite variations of the SMAS technique over the past 20 years. In this study, the nasolabial fold is shown to be part of the overall aging deformity that affects the cheek and perioral region. The relevant anatomy is reviewed and the safety of the procedure is assessed in a personal series of 135 patients. It is concluded that the two principles of this technique, that is, complete SMAS release and reattachment to the zygoma, safely and effectively achieve a natural-appearing rejuvenation of the cheek and nasolabial fold.

Stuzin JM, Baker TJ, Gordon HL, Baker TM. Extended SMAS dissection as an approach to midface rejuvenation. *Clin Plast Surg* 22:295-311, 1995.

The objective in rhytidectomy is to rejuvenate and improve facial appearance. To obtain consistent results, face lifting should be approached not just as a tightening or lifting procedure but also as a reconstructive procedure, reversing the anatomic changes that occur in aging. The authors discuss the blending of surgical technique, anatomic knowledge, and artistic sensitivity to individualize the surgical approach for patients. Furthermore, the authors stress that obtaining surgical rejuvenation while minimizing signs of surgical distortion should be the ultimate goal of face-lifting procedures.

CHAPTER 45

High SMAS Face Lift With Orbicularis Redraping and Septal Reset

FRITZ E. BARTON, JR.

The traditional method of soft tissue facial rejuvenation has been segmental, skin-based surgery. Most commonly, early signs of aging have been addressed with initial blepharoplasty, followed later by correction of the cheek and/or neck and occasionally, rejuvenation of the forehead. This approach was and still is popular for several reasons. First, the patient views it as logical to do multiple, small, stepwise procedures. The patient assumes that if less is done, the less likelihood that he or she will look “operated on.” Second, it seems less threatening when the procedures can be done with a local anesthetic and sedation, rather than with a general anesthetic. Third, the procedures are quick for the surgeon, and recovery is quick for the patient. Limited skin-based procedures, with or without superficial plication sutures in the SMAS, are simple in concept as well as in application.

In this chapter, I will present an approach that challenges most of those tenets.

I believe that paramount to the maintenance of facial beauty in aging is the maintenance of facial harmony. At any age, one of the requirements for looking natural is for all segments of the facial aesthetic complex—from the hairline to the clavicles—to match. Generalized laxity looks natural; generalized firmness looks natural. But a lax segment juxtaposed against a firm segment looks unnatural. As I explain to patients, no matter how skillfully you shorten two legs of a chair, it never looks in balance. Not only is this disharmony important initially, but as aging progresses, disharmony often becomes more apparent.

It is my firm belief that at the time of the initial facial rejuvenation surgery, changes that are present throughout should be treated simultaneously and comprehensively. I think that the subunits of the face and neck overlap. Thus mobilizing only one unit is restricted by the attachments of the adjacent units. Mobilizing and repositioning all of the subunits simultaneously allows a harmonious blending. Nowhere is this more important than in the lower eyelid and the cheek.

Pertinent Anatomy

Several surgical principles are incorporated in surgical planning. First, the cheek unit is dealt with as a single composite unit. Although some faces have significant facial atrophy with volume loss, descent is not only a prominent factor, but it is also the most correctable factor. The facial soft tissues, skin and subcutaneous fat, are attached to the facial skeleton by osteocutaneous fibrous connections—“ligaments” and fascias. Over time these supporting fibrous attachments relax, allowing descent, particularly of the superficial subcutaneous fat and skin. Just as the skin was not holding the soft tissues in place initially, it is not a useful layer for resupport. Skin is a viscoelastic structure, designed to be flexible and expansile. By definition, an elastic structure is

not a good choice for bearing the load of suspension. Dense collagenous structures, fascia and tendon, are designed to carry load. Therefore retightening the deep fascia is the best way to resuspend the facial fatty mass and skin.

Critics of this load-bearing suspension concept argue that any tension in a face lift creates flattening of the facial contours and should be avoided. I agree that any tension in the skin is to be avoided to avoid stress relaxation and a stretched look. Skin will not support even its own weight, much less the weight of the cheek mass. It is the skin tension from skin-based procedures that has produced the large number of stretched, distorted faces that have given face-lift surgery a bad name.

However, vertical repositioning of the subcutaneous facial mass by means of fascial (SMAS) advancement does not flatten contour or create skin tension.

The second principle in my approach is to leave skin attached to the SMAS and subcutaneous fatty mass, so the entire cheek moves as a whole. This approach is a modification of the original Skoog procedure.

Our previous studies have shown that the platysma/SMAS serves as a myocutaneous unit. After transection of the anterior branch of the superficial temporal artery with the surgical dissection, the branches of the anterior facial artery supply the midcheek skin via the platysma. Moreover, the SMAS sends fibrous connections through the overlying subcutaneous fat to the dermis. Therefore elevation of the subcutaneous mass through the SMAS indirectly advances the skin without causing direct dermal tension.

Some have criticized advancing the cheek as a composite of skin and SMAS, contending that the skin and SMAS cannot be redraped in different directions. I do not believe this opinion to be valid. First, as has recently become accepted, the best direction for redraping both the skin and the SMAS in the cheek is vertical. However, the neck often requires more horizontal (or oblique) redraping. Thus the skin and platysma are dissected as separate layers in the neck below the mandible.

The third principle is that advancement is facilitated by release. As previously discussed, the subcutaneous fatty mass and SMAS are fixed by retaining ligaments and fascial attachments. The fatty mass is secured by the zygomatic retaining ligament. The SMAS is restricted by its attachment to the parotid capsule as well as its investment of the superficial layer of the facial mimetic muscles. Advancement vertically is restricted by these attachments. Conversely, I believe that advancement is facilitated by release of these attachments. This approach is central to the debate over whether plication (infolding without undermining) is as effective as imbrication (undermining, advancement, and overlapping) in long-term maintenance of cheek suspension. Having performed both techniques for many years, I think that imbrication is more long lasting.

A wide variety of methods have been described for using the SMAS to elevate the subcutaneous facial fat. Early attempts at SMAS advancement were timid dissections only over the parotid gland. Because the SMAS is broadly laminated to the parotid capsule, the SMAS is immobile in this area. As a result, these initial experiences were disappointing, and the value of the SMAS was questioned.

With extended dissection, however, the restriction of the parotid capsule is released, and the areolar gliding plane over the buccal area is entered. With this maneuver, the cheek mass over the buccal and mandibular area is well mobilized. This step in the evolution of SMAS dissection I regard as a low SMAS technique, in that its effect is limited to below the zygomatic arch. The upper subcutaneous mass, or malar pad, is left unsuspended.

It was my goal to suspend the entire cheek subcutaneous mass, mandibular and malar, as a single unit to provide pansupport. In 1984, after several years of anatomic dissections and experience with sub-SMAS dissections in reconstructive cheek flaps, I performed my first high SMAS procedure. Other than several variations of the extent of anterior dissection, I have persisted with the original technique. As with any procedure, the application subtleties vary with each patient, but I have found the high SMAS face lift to deliver consistent, predictable, long-lasting benefits. Although the cheek mass suspension method remained rather constant, what I have added is the approach to the lower orbit and lid-cheek junction.

As with surgery of the cheek and neck, early lower blepharoplasty techniques focused on skin excess. I initially performed skin flap elevation and excision, in association with selective fat removal, for many years. In some patients, it was and remains an adequate technique. However, I began to observe that the result in many patients was not of the highest quality.

One group that failed with the skin flap technique was patients with so-called malar bags. It was not until the sentinel publications of Furnas describing *festoons* and Hamra observing the *orbicularis crescent* that I came to understand, and look for, the importance of orbicularis ptosis in lower eyelid surgery. Like many unnoticed deformities, the more you look for it, the more prevalent you realize it is. I am now convinced that orbicularis ptosis is present in essentially every aging eyelid. Thus orbicularis suspension in the lower eyelid is comparable to SMAS suspension in the cheek.

It is imperative to understand the partitioning of the orbit from the cheek to understand how to safely deal with the lid-cheek junction. Extending from the lacrimal bone medially to the inner orbit laterally, the fibrous sling encases the lower lid tarsal plate and soft tissue. The lower eyelid is a rather slight and fragile structure, so the suspensory apparatus can be delicate.

The cheek mass, by contrast, is much more massive, and accordingly, it is heavier. Unopposed, the weight of the cheek would overwhelm the fragile lid suspensory system and pull the lid down into ectropion. However, the eyelid is protected by two barriers.

The orbicularis retaining ligament (or orbitomalar ligament) extends from just below the orbital rim to the junction between the preseptal and periorbital orbicularis oculi. Originating medially at the orbital rim and extending obliquely downward through the cheek at the lower border of the periorbital orbicularis oculi is the zygomaticocutaneous ligament (or malar membrane). In combination, these two osteocutaneous ligaments serve as “check rein” partitions from which the weight of the cheek is partially suspended. As long as they are intact, the lower eyelid is protected. Procedures developed to blend the lid-cheek junction, however, frequently disrupt these barriers. To avoid potential ectropion of the lower eyelid with release of the barriers, protective independent suspension of the cheek should be done. This protection gains in importance as patients with increasingly negative-vector orbits are treated.

Operative Technique

To begin a high SMAS face lift, a preauricular skin incision is usually brought posttragally. The mastoid extent of the incision is determined by the degree of neck skin excess.

A limited subcutaneous dissection is carried out in the preauricular area to the extent of the estimated skin excision. The goal is to leave minimal undermined skin at the completion of the procedure. The subcutaneous dissection is continued above the zygomatic arch in a tunnel over to the lateral border of the orbicularis oculi.

The SMAS is then initially incised from the top of the tragus to the bottom of the earlobe to establish the proper plane over the parotid. It is at this location that the SMAS is thickest and the facial nerve is the deepest within the parotid gland.

With the sub-SMAS plane established, dissection is continued anteriorly to the border of the parotid, where it becomes areolar in nature. It is at this point that the facial nerves exit the parotid gland, and the dissection is switched from sharp to blunt spreading. With vertical spreading, the buccal dissection is carried into the area of the mobile SMAS. It is imperative to leave the translucent buccal fascia intact as a protection over the facial nerve branches.

At the lower extent of the sub-SMAS dissection, approximately 4 cm below the mandibular border, a small horizontal backcut is made to allow the SMAS to displace upward without restriction from the investing fascia.

Next the upper border of the SMAS is transected above the zygomatic arch over to the lateral border of the orbicularis oculi muscle. It is this maneuver that facilitates upward repositioning of the upper malar fat. It has also been the most controversial portion of the technique. Traditional teaching has been that transection of the SMAS at this level would sever the frontal branch of the facial nerve. However, that anatomic dictum is incorrect. In fact, the facial nerve branch courses deeper over the zygomatic arch, and the SMAS can be safely elevated and separated from it.

Once the upper SMAS is released above the zygomatic arch, it is severed from the zygomatic retaining ligaments and its investment of the zygomaticus major muscle. Using the visible border of the orbicularis oculi as a point of origin, the surgeon can identify the path of the zygomaticus major muscle. A thin layer of fat should be left on the muscle to protect the motor branch to the lateral orbicularis, which courses over the external surface of the zygomaticus major muscle origin. The plane of dissection is continued from beneath the SMAS over the external surface of the zygomaticus major muscle and into the subcutaneous plane, releasing the investing fascia connection of the SMAS.

The cheek mass is then relocated in a vertical direction and secured to the deep temporal fascia above the auricle. The periauricular SMAS is then reapproximated to provide a broad, secure closure. This vertical suspension of the cheek mass not only supports the cheek mass, but also provides something of a shelving support below the orbital tissues.

Orbicularis Suspension

The first step in orbicularis suspension is to perform a subciliary incision. The skin is then elevated over the pretarsal and preseptal orbicularis muscle. The lateral half of the orbicularis muscle is incised, leaving a pretarsal strip intact. Dissection is carried beneath the orbicularis muscle down to the level of the orbital rim. At this point the orbicularis retaining ligament and attachment over the zygomatic body are freed to allow mobilization. Without release of these attachments, the orbicularis muscle cannot be adequately mobilized superiorly.

A laterally based interpolation flap is then formed from the redundant upper edge of the orbicularis muscle. This muscular pennant is then tunneled beneath the superficial head of the lateral canthal raphe to be secured to the lateral orbital rim periosteum above. Tarsal protection during the healing phase is accomplished by either canthopexy or canthoplasty of the lateral canthal tendon. Redundant skin is then conservatively trimmed.

In patients with vector-positive orbits, only orbicularis redraping is necessary to smooth a prominent arcus marginalis.

Septal Reset

In patients with a negative-vector orbit, a prominent tear-trough configuration may be present consisting of malar bone deficiency, deep set arcus marginalis, and herniation of orbital fat. A septal reset procedure may be beneficial in addition to the orbicularis suspension and skin removal.

After elevation and release of the orbicularis muscle, the orbital septum is divided along the arcus marginalis. The orbital fat is extruded over the orbital rim. The orbital septum and orbital fat are then sutured together to the periosteum of the anterior orbital rim.

The remainder of the procedure of orbicularis suspension is then completed as previously described.

Benefits of the Combined Procedures

Although any of the aforementioned procedures can be performed alone, I think they are much more effective and much safer when performed together.

Effectiveness

The vertical elevation of the malar fat partially effaces the visible depression along the arcus marginalis, but it also transfers skin into the eyelid, usually necessitating lower lid skin removal. In addition, the malar fat elevation undercuts the redundant lower border of the orbicularis oculi, creating or accentuating a *malar crescent*.

Suspension of the orbicularis corrects this problem. In negative-vector patients with fat herniation, release of the orbital septum and reset of the orbital fat with the septum to the anterior orbital rim enhances the procedure.

Safety

From a safety viewpoint, independent suspension of the cheek protects the eyelid suspensory mechanism. To redrape the orbicularis oculi to correct orbicularis ptosis, release of the orbicularis retaining ligament is necessary. Furthermore, release of the malar membrane softens the oblique depression sometimes present across the cheek. The release of these osseocutaneous ligaments removes the protective partition between the lower eyelid and cheek. Independent vertical cheek elevation not only removes the weight of the cheek from the eyelid, but it also creates a “shelving” sling to support the eyelid.

For both reasons, when presented with a patient with aging in both the eyelid and cheek, I prefer to redrape them simultaneously, rather than sequentially.

Result

This 63-year-old woman has significant facial laxity, a negative-vector orbit with a tear-trough triad, and poor dermal tone. In my clinical experience, this type of patient is not uncommon, yet the quality of her tissue makes her challenging. She underwent a high SMAS face lift with orbicularis suspension and septal reset. She also had a simultaneous forehead lift. Her clinical result at 12 months postoperatively is shown.

Clinical Caveats

Faces age in all areas; therefore all aged areas should be addressed simultaneously to preserve facial harmony.

Skin undergoes stress relaxation. Therefore, to avoid a stretched look, skin should not be placed under tension.

The SMAS is the best “handle” with which to reposition the subcutaneous facial mass.

Leaving the SMAS attached to the skin allows the skin to be repositioned without tension.

Annotated Bibliography

CHAPTER 46

Lamellar High SMAS Face and Midface Lift:

*A Comprehensive Technique for
Natural-Appearing Rejuvenation of the Face*

TIMOTHY J. MARTEN

Traditional face-lift techniques have relied on the tightening of thin flaps of aging skin to elevate and support sagging deeper facial tissue. Although initial results from these procedures often appeared good, early recurrence of the original deformity was common, and poor scars and healing problems were frequently seen as a result of the obligatory wide flap undermining and unavoidable skin flap tension. These procedures also typically produced an easily recognized tight or face-lifted look that was usually exacerbated with subsequent procedures.

As plastic surgeons have pursued an improved outcome, our understanding of the aging process has improved, and face-lift techniques have evolved. Experience has since confirmed that an attractive, natural-appearing result is not possible without diverting tension away from the skin to the superficial musculoaponeurotic system (SMAS) and platysma and unless other deep layer structures and the aging midface are addressed. For many patients, an improved result is obtained if age-related facial atrophy is concomitantly corrected with fat injections or by other means (see Chapter 47).

Fundamental Concepts

Why Use the SMAS?

The fundamental flaw in “skin-only” face lifts, mini-lifts, and similar procedures is the fact that skin was meant to serve a covering function—not a structural or supporting one. Skin is inherently elastic and was intended to stretch and move as we express ourselves; it is not structurally capable of supporting sagging muscle, fat, and other structures that lie beneath it. Using skin as a vehicle to support sagging deep-layer tissue corrupts its covering function and results in abnormal skin tension and related secondary problems, including poor scars, tragal retraction, earlobe malposition, and a tight, unnatural appearance. Skin tension also flattens contour rather than restoring it, and because skin stretches as tension is applied, objectionable temple, sideburn, and occipital hairline displacement is common when skin-only techniques are used. In addition, because skin is inherently elastic and not capable of providing sustained support of deep facial tissues, the improvements achieved through most skin-only face lifts and mini-lifts are usually short lived.

Using the SMAS to lift sagging facial tissues and restore facial contour circumvents the problems associated with skin-only lifts as it is an inelastic structural layer capable of providing meaningful and sustained support. Although skin must be excised in SMAS procedures and proper excision will produce an improved result, only redundant tissue is sacrificed, and closure can be made under normal skin tension. Facial skin so treated will distribute itself naturally over new contours and is capable of some self-repair and contraction. This averts a tight or lifted appearance and further enhances the result.

Using the SMAS and platysma to elevate sagging facial tissues and to create an attractive face and neck contour provides a means by which sustained support can be obtained from nonelastic, structural tissue layers, and tension can be transferred away from the skin. This results in a soft, natural facial appearance, high-quality scars, and often doubles or triples the lifespan of the improvement. Diverting tension to the SMAS and platysma and away from the skin also preserves delicate preauricular contours and minimizes displacement of temporal and sideburn hairlines. In addition, unlike skin-only face lifts and mini-lifts in which subsequent procedures worsen skin tightness and problems associated with it, SMAS face lifts, at least in theory, can be repeated as often as needed without producing skin tightness and an abnormal appearance. This removes the “two face-lift limit” set by many surgeons performing skin-only procedures and allows patients to undergo procedures at an earlier age and more frequently, if desired.

Sustained and attractive support of the deep layers of the face cannot be predictably obtained by the placement of long “suspension” and “cable” sutures, even if soft, partially elastic materials are used. These “suture lift” procedures have led to a variety of problems for many patients, including suture extrusion, traction dimples, visible bowstringing, nerve injuries, facial dyskinesias, chronic pain syndromes, and an abnormal appearance on animation. Suspension sutures placed in the neck can also create a tight or choking feeling that is disturbing to patients, and can result in difficulties in speaking and swallowing. In addition, if large, stiff, permanent sutures are used, the suture knots and the sutures themselves can often be felt beneath the skin. In some cases these suture knots can erode overlying skin, necessitating their removal.

The fundamental flaw in “suture lifts” and the use of suspension sutures is that one must rely on a small, rigid thread to support a large area of delicate, inherently soft, mobile facial tissue. Over time, these sutures “cheese-wire” through the tissues they were intended to support and can injure important neuromuscular structures. Suspension sutures also prevent natural depression and downward movement of facial tissues, impeding certain expressions and creating an unnatural appearance.

Unlike suspension suture placement, SMAS elevation allows secure, balanced elevation of facial tissues without disruption of their natural relationships. Tissue anchoring is achieved through direct tissue contact and healing, not distant point suspension by a suture. SMAS elevation also allows natural gliding and depression of tissue and a more natural appearance on animation.

The periosteum has been advocated by some as the layer beneath which face-lift dissection should be performed and the layer by which sagging deep facial tissues should be elevated. When properly performed, such procedures divert some tension away from the skin and avoid many of the problems associated with skin-only procedures.

Improvement in the infraorbital and upper midface areas may also be obtained in some cases when the procedures are properly designed. However, this layer is a conceptually illogical choice for overall rejuvenation of the face in that it is densely adherent to the facial skeleton and does not significantly descend as part of the aging process. It is also not closely associated with the intermediate layers of the face, where most of the aging is known to occur, and its dissection results in prolonged swelling and induration and generally portends a longer recovery period for the patient. In addition, many subperiosteal face-lift techniques rely on the concomitant use of suspension sutures; thus these procedures often share many of the related problems. Unlike the periosteum, the SMAS is closely associated with tissues that sag as the face ages and actually envelopes many, if not most, of those of concern. It is thus arguably a more logical layer to use to restore them to a more youthful position.

The SMAS and the Midface

The midface is generally defined as an inverted triangular area situated over the anterior upper cheek that is bounded by the zygomaticus major muscle laterally, the nasolabial fold medially, and the infraorbital rim superiorly. In healthy, youthful-appearing individuals this area is full and confluent with the adjacent cheek and lower eyelid. As men and women age, however, and enter their early midlife and beyond, there is a general wasting of and loss of volume from this area. Over time, this results in a loss of the smooth, youthful transition from the lower eyelid to the cheek and eventually leads to an ill, haggard, elderly appearance. Midface atrophy is felt by some surgeons to also be accompanied by descent of midface tissues, and the aging change seen in the upper cheek area is thus often referred to as *midface ptosis*.

The recognition of midface ptosis as a significant component of the changes occurring in the aging face, combined with the realization that the traditional SMAS face lift produced little or no improvement in the midface region, has led to the development of a variety of procedures designed to specifically target the midface area. Many of these techniques are now being performed as isolated procedures or in conjunction with lower eyelid surgery.

Although there is merit in the idea of rejuvenating the midface, isolated midface lift procedures are still evolving and have not been perfected. Most procedures have a steep learning curve and have been fraught with complications, especially when performed through a blepharoplasty incision. These complications include lid retraction, ectropion, canthal displacement, and dry-eye problems. As a result, many midface lift techniques have come to incorporate potentially problematic aggressive adjunctive surgical maneuvers, including canthotomies, canthoplasties, and orbicularis oculi muscle suspensions to prevent these problems from occurring. These maneuvers often result in a “changed look” that is disturbing to many patients and carry a high risk of significant and troublesome complications of their own.

Many other arguments can be made against the use of isolated midface procedures, including the fact that attractive rejuvenation of the face is possible without complete elimination of the nasolabial fold. Most patients with nasolabial folds had them when they were young, and their presence reflects the patient's anatomic makeup, not necessarily an age-related, undesirable change. In such cases it is neither necessary nor desirable to completely eliminate them, because they are an inherent and appropriate feature of the patient's face. As a practical matter, however, most of the improvement obtained by midface lifts consists only of elevation of the lid-cheek junction, not correction of the nasolabial fold. Midface lifts also produce a subtle improvement that is not always noticed or appreciated by the patient. Because of this, time in the operating room is often arguably better spent on lower-risk maneuvers that result in more noticeable improvement that is of higher priority to the patient.

Careful evaluation of most patients who request a midface lift will show that they also need a face lift. It is rare to encounter a patient with midface aging who does not also have sagging in the cheek and jowl, and midface lifts are arguably more logically performed in conjunction with a formal face-lift procedure. When this is done, improvement is more balanced and comprehensive, producing a more harmonious and natural-appearing result. Healing is also faster and complications are less likely if midface improvement can be obtained through the face-lift incision rather than through a blepharoplasty or intraoral approach.

Most midface lifts are also generally conceptually flawed in that they are based on the erroneous assumption that the problem seen in the anterior upper cheek is solely one of tissue sagging. Failure to acknowledge the fact that *atrophy* is present to a significant degree in most cases has led to general disappointment following many procedures for both patients and surgeons and has resulted in the addition of dermal fat grafts, orbital fat transposition, and "septal resets" to midface lift procedures. However, it remains to be answered whether these procedures can restore lost volume as simply, naturally, and effectively as with fat injections.

The High SMAS Lift

The conventional low cheek SMAS flap elevated below the zygomatic arch suffers the drawback that it cannot by design have an impact on tissues of the midface and infraorbital region. Low designs target the lower cheek and jowl only and produce little if any improvement in the upper anterior cheek area. Planning the flap "higher," along the superior border of the zygomatic arch, and extending the dissection medially to mobilize midface tissue overcomes this problem and produces an improved result.

Low SMAS. A, Plan for a low SMAS procedure. Note that the upper border of the flap lies *below* the zygomatic arch. **B,** Low SMAS flap after dissection and suspension. The area of flap effect (*green circle*) is limited to the lower cheek and jowl, and no improvement is obtained in the midface, infraorbital, or perioral regions (*black circle*).

High SMAS. C, Plan for a high SMAS procedure. Note that the upper border of the flap lies *over* the zygomatic arch. **D,** High SMAS flap after dissection and suspension. The area of flap effect (*green circle*) includes not only the cheek and jowl, but also the midface, infraorbital, and perioral regions (*black circle*).

Benefits include restoration of a youthful upper cheek contour, an aesthetically significant fill of the infraorbital region, increased support of the lower eyelid, and correction of the nasolabial fold, all without the need to perform a separate or distinct midface lift. High SMAS procedures are also readily combined with midface fat injections, because midface and infraorbital tissue planes are not opened or dissected. This averts the need to perform complex and potentially problematic procedures in which orbital fat is transposed, the orbital septum “reset” or free grafts are placed.

At least part of the popularity of low SMAS designs can be attributed to perceived anatomic constraints about the zygomatic arch and laudable efforts to design flaps that could be dissected safely without jeopardizing the frontal branch of the facial nerve. However, careful reappraisal of this assumption has shown that high dissection is anatomically sound and clinically safe. For many if not most patients, the repositioning of midface tissue obtained with a high SMAS flap is satisfactory, and no additional or separate midface lift procedure is required.

Lamellar Dissection and Bidirectional Tissue Shifts

A number of specific strategies that merit review have been devised for use of the SMAS. These include composite dissections in which the SMAS and skin are elevated as a single unit and advanced in the same direction, and “lamellar” dissections in which skin and SMAS are elevated as separate layers and advanced bidirectionally along different vectors. Composite-type dissections have the potential advantage of being quicker to perform, and they result in a comparatively thicker, arguably more durable flap composed of both skin and SMAS. However, these dissections have the distinct disadvantage that skin and SMAS must be advanced the same amount, in the same direction, and suspended under more or less the same amount of tension. Because skin and SMAS age at different rates and along somewhat different vectors, optimal treatment of each layer is generally not possible when these techniques are employed, and skin overshifting, skin overtightening, hairline displacement, “wrinkle shift” from the neck to the cheek, and other objectionable occurrences and unnatural appearances can result. In addition, if the orbicularis oculi is included in a composite flap, the muscle’s motor nerve supply can be compromised and lid dysfunction, nerve cross-regeneration, and other disturbing and objectionable abnormalities can result.

Lamellar dissections offer the distinct advantage that skin and SMAS can be advanced different amounts, along separate vectors, and can be suspended under differential tension. This allows each of these layers to be addressed individually, avoiding skin tension, hairline displacement, and objectionable wrinkle shifts. This in turn results in a more natural appearance, a more comprehensive rejuvenation, and fewer secondary deformities. Lamellar techniques have the potential drawbacks that the SMAS flap is thinner and more fragile and that the dissection is technically more demanding and time consuming to perform.

Lateral Sweep

Traditional skin-only face lifts and low SMAS procedures typically resulted in over-tightening of the lateral cheek skin and provided little support of the perioral area and jowl. In time, these unsupported tissues continued to descend in a disproportionate fashion, resulting in a characteristic and objectionable “upswept” appearance. Although the unsupported tissue responsible for this problem is actually anteriorly situated, and it is perhaps more correctly referred to anatomically as an *anterior* phenomenon, this unattractive occurrence has come to be known as *lateral sweep*. Lateral sweep is generally most apparent in the lateral view when the patient looks down. In this position, lateral facial tightness is increased as a result of better tissue fixation in the preauricular area, and the “sweep” appearance is accentuated because of the comparatively poor support and fixation in the perioral and jowl areas.

Lateral sweep is an unavoidable eventual consequence of all traditional skin-lift, low SMAS, and low composite procedures. These skin-only and low deep-layer procedures are not capable of providing uniform support to both the anterior and lateral cheek and are biogeometrically inclined to produce an unbalanced, unnatural appearance. A high SMAS flap, in contrast, provides simultaneous uniform support of the lateral facial, midface, and lateral perioral areas. This results in a more balanced, comprehensive, and natural rejuvenation.

Lateral sweep can result when a high SMAS technique is used if the lateral perioral region is overdissected subcutaneously and ligamentous attachments between the SMAS and the skin are mistakenly and inappropriately divided. These ligaments are the means by which the high flap supports the lateral perioral area, and overdissection of this sort is a common error made by surgeons who erroneously assume that extended skin undermining will help improve the nasolabial fold. This is not a flaw in the technique; it is merely a failure to perform the procedure correctly.

Recognizing the Aging Deformity

Recognizing the elements of the aging deformity and appreciating the underlying anatomic changes are essential to properly advising patients and fundamental to the planning of any surgical repair.

Many if not most of the changes associated with loss of facial contour represent primarily deep-layer problems that will be inadequately corrected with traditional skin-only or low SMAS techniques. Regrettably, surgeons unfamiliar with deep-layer techniques often employ skin-only face lifts or mini-lifts and resort to misguided and misapplied ancillary procedures to overcome the shortcomings of these methods. These procedures include facial liposuction, buccal fat extraction, malarplasty, submalarplasty, geniomandibular groove augmentation (a prejowl implant), PTFE (Gore-

Tex) implantation, and various types of suspension suture placement. Although some of these procedures are sometimes indicated, they will be unnecessary in most cases if a high SMAS face lift and deep-layer rejuvenation are performed.

High SMAS face lift. **A,** This 47-year-old woman is shown before surgery. Note the loss of youthful contour. **B,** She is shown following a high SMAS face lift, neck lift, forehead lift, upper and lower blepharoplasties, and fat injections. Sagging tissues have been repositioned, her youthful jawline contour restored, and redundant skin has been excised without producing a tight or pulled appearance.

Patients with significant *facial atrophy* and age-related facial wasting will generally achieve suboptimal improvement from both surface treatments of facial skin and surgical lifts. Smoothing the skin will not hide a drawn appearance caused by the loss of facial volume, and it is difficult to create natural, attractive contours by lifting and repositioning tissues that have abnormally thinned and deflated with age. Restoring lost facial volume using fat injections is a powerful technique that has gained increased acceptance by plastic surgeons and other physicians who treat the aging face. When properly performed, the addition of fat to areas of the face that have atrophied from age or disease can produce a significant, sustained improvement in appearance that is unobtainable by other means. However, age-related facial atrophy rarely exists in isolation in a healthy individual; thus patients troubled by it are not always appropriately or logically treated by fat injections alone. Isolated fat injections are also of questionable benefit to a patient with significant facial sagging and skin redundancy. Although aggressive filling of the sagging face with fat can improve the facial contour, it generally results in an unusually large, overfilled face that appears both unnatural and unfeminine. Such an overfilled face is hard to correct attractively at a later date. It is both more logical and practical to perform fat injections in conjunction with formal surgical lifts if needed, or after ptotic tissue has been repositioned and redundant tissue has been removed. When a high SMAS tech-

nique is used in conjunction with fat injections, both loss of contour and facial atrophy can be corrected and optimal improvement can be obtained.

Panfacial Rejuvenation

Rarely does isolated aging occur in the lower face and neck, and nearly all patients who request face-lift surgery need to undergo some sort of forehead and eyelid surgery as well. Many are confused, however, by the term “face lift” and take it to imply correction will be made in all areas. These patients must be counseled carefully, because *the face lift itself will produce little if any improvement in upper facial deformities and in fact tends to unmask and draw attention to them.*

It is not uncommon for patients concerned with aging in their lower face and neck to question the need to undergo forehead surgery. Many unconsciously optimize their forehead appearance when looking in a mirror by raising their eyebrows, or they try to conceal the signs of forehead ptosis by aggressive plucking the lateral eyebrows or by futilely trying to hide dense transverse forehead wrinkles with hairstyles that conceal the forehead. Although chemodenervation with *botulinum* toxin injections (such as Botox or Dysport) can smooth forehead expression lines by relaxing hyperactive muscles and in some cases can be used to produce some lateral brow elevation, these injections cannot correct advanced brow ptosis. Failure to properly advise patients and perform forehead surgery can result in the disharmonious appearance often referred to as the *young face–old forehead deformity*.

It is also not uncommon for patients to request that surgery be performed on their neck only. Although such a plan is acceptable for some men, failure to concomitantly restore attractive cheek contour and lift sagging jowls in women generally results in an unnatural and unfeminine appearance. In addition, if an aggressive “corset” platysmaplasty is performed as part of an isolated neck lift, sagging in the cheeks and jowl area can be accentuated, because platysma tightening exerts a downward pull on tissue in these areas.

Face-lift surgery can unmask other existing deformities and create a need to perform additional procedures. This is commonly seen on the lower eyelid, where the ptotic cheek often smoothes lower lid skin preoperatively by dragging it inferiorly. *Properly executed repositioning of the midface and malar fat pad will usually result in some lower lid wrinkling and redundancy that was not present before surgery.* This can be demonstrated before the procedure to the patient by elevating the cheek to the predicted postoperative position while the patient holds a hand mirror and pointing out the resulting wrinkling in the lower lid area. In these cases some excision of lower lid skin must be made (or resurfacing performed), even if the lid appears smooth before surgery, if lower lid wrinkling is to be avoided postoperatively. It is also for this reason that lower blepharoplasty should be performed *after* face-lift surgery is complete, not at the beginning of the procedure.

Preoperative Planning

It is not possible to design or use a universal face-lift technique, and this is the fundamental flaw of all formulaic, “franchise,” “infomercial,” and other “cookie-cutter” types of face-lift procedures. Each patient has a unique set of problems that require precise anatomic diagnosis and an appropriately planned and individualized surgical repair. Committed study and careful planning will maximize improvement, limit complications, and minimize the secondary deformities commonly seen after an ill-conceived and inappropriate “one-size-fits-all” procedure.

Planning the Temple Incision

The temporal portion of the face-lift incision has traditionally been placed within the temporal scalp in a well-intended but often counterproductive attempt to hide the resulting scar. When cheek skin redundancy is small and abundant temple and sideburn hair is present, such a plan can be used without producing objectionable sideburn elevation and temporal hairline displacement. Patients best suited for this incision plan are usually young, with mild cheek laxity only. In many other situations, however, larger skin shifts and the presence of sparse temple hair can result in unnatural, telltale shifting and displacement of the temporal hairline and sideburn.

Displacement of the sideburn and temple hair as a result of poor incision planning.

In this woman the temporal portion of the face-lift incision was made in the temporal scalp in a well-intended effort to hide the resulting scar. Because the cheek flap redundancy was large and skin elasticity was poor, advancement of the cheek skin flap resulted in objectionable hairline displacement. An incision along the hairline would have prevented this deformity. Proper analysis, careful planning, and the use of an incision along the hairline, when indicated, can avert this problem without compromising the overall outcome of the procedure.

Healed incisions along the temporal hairline. The use of an incision along the hairline, when indicated, can prevent hairline and sideburn displacement without compromising the result. Although a fine scar is present along the hairline in each of these patients, it is not evident on casual inspection. Note the preservation of lush temple hair and a full, youthful, natural-appearing sideburn (compare with the patients shown on p. 1535).

In choosing the location of the temporal portion of the face-lift incision it is important to note the distance between the lateral orbit and the anterior aspect of the temporal hairline as this distance is aesthetically significant and increases with age.

Assessing temporal skin show. The distance between the lateral orbit and the temporal hairline and how it will change with skin flap shift must be considered when planning the temple portion of the face-lift incision.

In healthy, youthful-appearing individuals the distance between the lateral orbit and temporal hairline usually measures no more than 4 to 5 cm, but in older patients or in those who have had a prior face lift, it will often be seen to be considerably more.

Equally important as this distance is the surgeon's estimate of the skin redundancy over the upper cheek, and thus the skin shift that will occur when the face-lift flap is lifted. This can easily be assessed by simply pinching up redundant skin and measuring it. *Skin redundancy over the cheek, when considered in conjunction with the amount of existing temporal "skin show," allows rational selection of the best site for placement of the temporal incision.*

In patients in whom minimal or modest temporal skin shift is predicted to occur using the preceding method of analysis and for whom the temporal hairline will remain within 5 cm of the lateral orbit, the temporal portion of the face-lift incision can be placed in the traditional location 4 to 5 cm within the temporal scalp, extending superiorly from the anterior-superior aspect of the ear.

Plan for incision on temporal scalp. This plan is used for patients predicted to have minimal or modest shift of sideburn and temple hair after elevation of the cheek flap. It will *not* be appropriate for all patients.

When analysis of the amount of temple and sideburn hair present and the degree of redundant cheek skin that exists suggests the temporal hairline will be shifted more than 5 cm away from the lateral orbit and/or the sideburn hair shifted above the junction of the ear with the scalp, one should consider placing the incision along the hairline rather than within the temporal scalp.

Plan for incision along the temporal hairline.

An incision along the temporal hairline should be considered whenever objectionable displacement of the sideburn and temple hair is predicted.

This incision will accommodate large posterior-superior skin flap shifts and allows maximal improvement in the upper lateral face to be made without objectionable displacement of the temple and sideburn hair. If it is made with care *and closed under no tension*, the resulting scar is usually inconspicuous and far less troublesome for the patient than a displaced hairline would be (see p. 1535).

In light of the preceding discussion it can be seen that the position of the temporal portion of the face-lift incision cannot be arbitrary and must be based on the patient's individual anatomy, and options for the placement of the temporal portion of the face-lift incision should be discussed with any patient in whom significant displacement of the temporal hairline or elevation of the sideburn might occur. Incision placement is best presented as a choice between two imperfect alternatives and it is wise that the final decision as to where the incision will be located be left to patient after appropriate discussion has been made. Placing the incision in a traditional location within the temporal scalp (see p. 1537) will help conceal the scar, but often

at the expense of a large and objectionable displacement of the temporal hairline and sideburn, and compromised improvement over the temporal face. Inappropriate use of a temporal scalp incision inevitably results in an old and unnatural appearance that is usually immediately obvious, even on a casual glance and at a distance. An incision along the hairline, however, will prevent hairline displacement, and although a scar will undeniably be present where the incision was made, it is usually inconspicuous and will not be noticed by others. In addition, although a suboptimally healed incision along the hairline can be concealed with makeup or tattooed or revised, a significantly displaced hairline is difficult to conceal and a challenge to correct. It has been my experience that most patients are disturbed by the prospect of temple and sideburn hair displacement and recognize this occurrence as a telltale sign that a face lift has been performed. When counseled properly and given the choice, most will readily consent to incision placement along their hairline.

Planning the Preauricular Incision

Open to scrutiny, the preauricular region exists as a frequent point of reference for those seeking to identify a face-lift patient. Traditionally, incisions here are made well anterior to the anterior border of the helix and continued inferiorly, anterior to the tragus.

Traditional location of the preauricular incision. This plan places the scar in an area open to inspection by others and “brands” the patient as having had face-lift surgery. Makeup will not conceal a scar in this location, because the scar is smooth and the skin on either side of it not. Placing the incision in this location will also typically result in a difference of skin color on each side of the resulting scar—an additional telltale sign that surgery has been performed.

This design, however, works well only for the unusual patient with cheek and tragal skin of similar characteristics who also exhibits favorable healing. Unfortunately, most patients have a marked gradient of color, texture, and surface irregularities over these areas, and a telltale mismatch will be evident on each side of the scar, even if the scar itself heals inconspicuously. For these reasons, and *in all but the unusual case, the preauricular portion of the face-lift incision should be precisely placed along the posterior margin of the tragus, rather than in the pretragal sulcus.*

Marginal tragal (“retrotragal”) plan for the preauricular portion of the face-lift incision.

Placing the incision along natural anatomic contours conceals the scar and disguises differences in color and skin texture on each side of it. Note that the preauricular incision is composed of a prehelical, pretragal, and prelobular component incision.

In this location a mismatch of color, texture, or surface irregularities will not be noticed (or will appear appropriate), and the scar, if visible, will appear to be a tragal highlight.

Comparison of pretragal and marginal tragal (retrotragal) incisions. *Left,* In this patient the pretragal incision has healed satisfactorily, but the resulting scar is visible because of differences of color and texture on each side of it. *Right,* The same patient is seen after a secondary face lift in which the incision was moved to the posterior margin of the tragus (the retrotragal position). Color and texture differences, and the scar itself, are now hidden along natural anatomic interfaces.

In addition, and despite some claims to the contrary, a properly planned and executed incision along the *margin* of the tragus will not produce tragal retraction or other anatomic irregularity.

Healed retrotragal incisions. Close-up views of face-lift patients with preauricular incisions along the margin of the tragus. Scars are well concealed, and no tragal distortion is present.

In a man, the tragus can be kept free of beard hair by intraoperative destruction of beard follicles from the underside of the tragal flap.

Retrotragal incisions in male patients. In these men, the incision has been made along the posterior margin of the tragus in the same general plan as was used for the female patients shown above. This avoids a pretragal scar that is typically difficult for a man to conceal. The tragus is kept free of beard hair by intraoperative destruction of beard follicles from the underside of the tragal flap. This is accomplished by folding the tragal skin flap over the index fingertip of the surgeon's nondominant hand using small skin hooks and applying low electrocautery current to exposed beard follicles with a needle-tipped cautery instrument. Loupe magnification facilitates accurate destruction of individual follicles.

The superior (prehelical) portion of the preauricular incision should be planned as a soft curve paralleling the curve of the anterior border of the helix. This will result in a natural-appearing width to the helix in keeping with the rest of the ear, and the resultant scar, if visible, will appear to be a helical highlight. As the tragus is approached, the mark for incision is carried into the depression superior to it and then continued along the *posterior tragal margin*. In this location the scar, if visible, will appear as a natural highlight. *It is unnecessary and an error to place this incision in a retrotragal position on the inner surface of the tragus. This usually results in a bulky, amorphous-appearing tragus and obliteration of tragal anatomy.*

At the inferior portion of the tragus, the incision must turn anteriorly and then again inferiorly, into the crease between anterior lobule and cheek. If a more relaxed design is used, or if a straight line incision is made, skin settling and scar contraction will result in crowding of the incisura, obliteration of the inferior tragal border, and a telltale elongated and chopped-off tragal appearance.

“Chopped-off” tragus. An unnatural-appearing, elongated tragus with an indistinct inferior border results from poor incision planning and improper excision of skin during incision closure.

Planning the Perilobular Incision

To obtain a natural perilobular appearance, it is essential to preserve the natural sulcus between the earlobe and cheek and to avoid destruction of or excision of this and aesthetically important anatomic subunit. This is accomplished by marking the incision 1 to 2 mm inferior to this junction. All other factors being equal, a superior result will be obtained when such a plan is used, in comparison to any plan in which the incision is placed directly in the sulcus and an attempt is subsequently made to directly join a thin, soft earlobe with a coarse, thick cheek.

Planning the Postauricular Incision

Traditionally, the postauricular portion of the face-lift incision has been made over the posterior surface of the concha. This was done as part of a well-intended effort to offset the inevitable descent of the postauricular flap and inferior migration of the resulting scar that occurred when the skin was tightened in an attempt to improve neck contour. Many surgeons have come to realize that such a plan embodies erroneous assumptions and can result in undesirable effects, including hypertrophic scarring, postauricular webbing, and obliteration of the auriculomastoid crease. In addition, a scar on the posterior surface of the concha will not migrate inferiorly if the flap has been shifted and trimmed correctly and is suspended under minimal or no tension. It may thus be visible to those sitting behind the patient in some settings.

The postauricular portion of the face-lift incision should be marked directly in the existing auriculomastoid groove and the mark turned posteriorly at the approximate level of the anterior crus of the antihelix. *Marking must be made with the ear resting near its natural anatomic position. If the ear is pulled forward while the marks are made, mastoid skin will be pulled anteriorly over the posterior surface of the concha, and the incision will end up posterior to its intended location.* Incorrect marking in this manner is one of the most common causes of a poorly situated postauricular scar.

Planning the Occipital Incision

Planning the location for the occipital portion of the face-lift incision is conceptually similar to that for the temple region, and the incision plan must address similar concerns of hairline displacement and scar visibility. Traditionally this incision is arbitrarily placed transversely, high on the occipital scalp, in a well-intended but usually counterproductive attempt to hide the resultant scar.

Traditional plan for the occipital portion of the face-lift incision. The incision is made transversely into the occipital scalp in a well-intended but usually counterproductive attempt to hide the resultant scar. This incision plan should be used for access to the upper lateral neck only in younger patients and patients with minimal neck skin excess as it does not allow skin to be excised without notching of the occipital hairline (see p. 1544).

For patients with a minor redundancy of neck skin for whom excision of postauricular skin is unnecessary, such a plan is appropriate and will result in a well-concealed scar. Patients in this category are usually young and have only a mild neck deformity. In these cases *the incision is used for access to the lateral neck only, not as a means to remove postauricular skin*. Skin excision using this incision plan will result in the advancement of neck skin into the occipital scalp and notching of the occipital hairline.

Notching of the occipital hairline.

Notching of the occipital hairline is seen in these two patients, whose surgeons inappropriately used traditional occipital incision plans.

Although not all patients will recognize this deformity for what it is, most are nonetheless self-conscious about it, especially if they wear their hair up or back or lead active outdoor lives where activities, wind, and water may displace camouflaging wisps of remaining hair. Proper analysis, careful planning, and the use of an incision along the hairline, when indicated, can avert this problem without compromising the result.

Healed incisions along the occipital hairline.

Both of these patients are seen after surgery in which an incision along the occipital hairline was used. If this incision is planned carefully and properly closed, notching of the hairline is averted and an inconspicuous scar will result.

In choosing the location of the occipital portion of the face-lift incision, the surgeon must estimate the skin redundancy along the predicted posterior-superior direction of flap shift. This can be accomplished by pinching up tissue over the upper-lateral neck and measuring it. If 2 cm or less of excess neck skin is present, a “traditional” incision over the mastoid extending posteriorly into the scalp at the level of the mid ear (see p. 1544) will not, in most cases, result in an objectionable disruption of the occipital hairline. If more than 2 cm of neck skin redundancy is present, however, the incision should be placed along the occipital hairline but be designed so that a telltale scar will not be visible in front of the fine hair on the nape of the neck. This can be accomplished by turning the inferior portion of the incision back into the scalp at the junction of thick and thin hair. From a practical standpoint, the traditional incision on the occipital scalp should be used for access to the neck only and closed without skin flap shift or advancement. Any patient with significant neck skin redundancy will require an incision along the occipital hairline if skin is to be advanced and excised in a biogeometrically correct fashion and hairline displacement is to be avoided.

Plan for an incision along the occipital hairline. The incision is planned so that its inferior portion turns posteriorly into the occipital scalp at the junction of thick and thin hair. This incision plan allows excess neck skin to be excised biogeometrically, prevents hairline displacement, and produces a well-concealed scar.

As is the case with temporal incision placement, options for placement of the occipital portion of the face-lift incision should be discussed with the patient and presented as a choice between two imperfect alternatives; it is wise to let the patient make the final decision after the advantages and disadvantages of each location have been discussed. Although an incision along the hairline is usually inconspicuous, even on close inspection, a scar will undeniably be present. Placing the incision within the scalp may help conceal the scar but will usually do so at the expense of objectionable displacement of the occipital hairline. Although a suboptimally healed incision along the hairline can be revised, tattooed, or easily concealed with an appropriate hairstyle, a significantly displaced hairline is difficult to conceal and a challenge to correct. It has been my experience that most patients are disturbed by the prospect of occipital hairline displacement and recognize it as a telltale sign that a face lift has been performed. When properly counseled and given the choice, most patients will readily consent to an incision along the hairline.

Short-Scar Face Lift

The idea of shortening the incisions used for facial rejuvenation procedures is appealing to patients and surgeons alike. Indeed, the first face-lift procedures performed some 100 years ago consisted of small excisions of the skin near the ear and along the frontal and occipital hairlines. Ironically, and despite the many important advances in techniques to rejuvenate the face that have been made over the past century, as non-plastic surgeons have begun to perform aesthetic surgery procedures and market their services, a new emphasis has been placed on ill-conceived “short-scar” procedures of questionable value and that are nonetheless deceptively appealing to almost any patient. Although some short-scar techniques, such as a limited-incision forehead lift, have merit and have provided new and better options for many patients, skin redundancy remains a consistent and undeniable problem for the surgeon seeking to rejuvenate the face and neck, and shorter incision plans involve significant compromises in the overall improvement that can thus be obtained.

Short-scar incision plans suffer the significant drawbacks that they limit access to deep-layer structures and prevent redundant skin from being shifted along proper vectors that produce the most improvement and the most natural appearance. Typically, manipulations of deep-layer tissues performed through short-scar incision plans are ineffectual at best, and more often result in damage to or mutilation of the SMAS. Shorter incisions also require that skin be gathered up when sutured and prevent it from being excised in a smooth, well-tailored manner.

A longer scar, conversely, allows skin flaps to be shifted in a geometrically correct fashion (see p. 1544, *bottom*) and skin to be excised without objectionable puckering or gathering, as seen above.

Interestingly and somewhat perplexingly, most short-scar procedures focus on the postauricular area and seek to shorten the postauricular scar. This scar is situated in a well-concealed area, however, and if tension is diverted to deep-layer tissue and

skin excision is carefully planned and properly executed, an inconspicuous scar will usually result. A scar in the postauricular area is arguably less obvious, easier to conceal, and overall less disturbing to the patient than is a shorter but irregular, puckered scar. Shortening a scar under these circumstances in a concealed area defies logic and is of questionable value to the patient.

Perhaps the most difficult to understand aspect of short-scar incision plans is that to minimize puckering and gathering behind the earlobe, the cheek skin flap is shifted along a vector that is directed too superiorly, necessitating a scar along the far less well concealed sideburn and temporal hairline. Although an incision is sometimes required in this area in certain patients to prevent hairline displacement, as previously discussed, shortening a scar in a concealed area by shifting it to a more visible area is of dubious value to a patient who might not have required it.

Ironically, it is younger patients, whose fears of longer scars can easily be played to, who are typically thought of and said to be the best candidates for short-scar procedures. It is this group of patients, however, who are disproportionately burdened by a more visible scar along the temporal hairline that would typically heal more favorably and be of less concern to an older patient. When the patient is properly counseled and given the choice, I find that younger patients are relieved to learn that a scar along the temporal hairline is not necessary in most cases and that it can be instead hidden in the temporal scalp and along the hairline behind the ear.

Comparison of long- and short-scar face-lift incision plans. *Left*, Most short-scar plans seek to shorten the incision in the postauricular area. To avoid puckering and gathering behind the lobule (see p. 1546), a vertical vector is applied to the cheek skin flap, necessitating an incision along the temple hairline as shown. Total scar length is approximately 12 cm. *Right*, A typical "long-scar" plan. The temporal part of the incision (*white dashed line*) is hidden in the temporal scalp and if properly closed will be difficult to find. The total length of *visible* scar (*red dashed line*) is 12 cm—no different from the short-scar plan. However, no scar is present in the highly visible area along the temporal hairline.

The final misconception about short-scar procedures involves the idea of the length of the scar itself and the fact that it is the amount of *visible* scar that matters, and whether the scar is *concealed* or not. If the amount of scar present in potentially visible areas is measured, there is no actual difference between that present in typical short-scar and long-scar procedures. In this sense, the term short-scar is a misnomer, because the visible scars from short- and long-scar incision plans are in reality the same length.

When asked what motivated them to adopt a short-scar face-lift technique, many surgeons cite poor healing in the postauricular area as the overriding impetus. Inherent in such a claim, however, is the notion that the postauricular area somehow heals in a different way from the other areas of the face and in a consistently aberrant manner. In reality, their answer reveals that they have simply been performing the procedure incorrectly. Two avoidable problems are typically put forth as the reason for avoiding a postauricular scar: hairline displacement and wide (or irregular and hypertrophic) postauricular scars. Hairline displacement results from inappropriate use of a traditional postauricular incision plan made into the occipital scalp. Wide, irregular, and hypertrophic scars are the result of ill-conceived attempts to create contour in the neck by tightening neck skin. Both these problems are readily avoidable, as discussed earlier and later in this chapter.

Ultimately, the purported advantages of short-scar procedures rest largely in their appeal to patients—and their allure and marketability on that basis. This, coupled with the growing demand for simplified face lifts, will likely ensure that such short-scar procedures will be with us in some form for some time to come. Nonetheless, the onus is on all physicians engaging in facial rejuvenative surgery to act in the best interest of the patient and to plan incisions to best suit each patient's circumstances. We must not simply do what is convenient, easily marketed, and quickly performed.

Drawbacks of Short-Scar Procedures

- Shortening the scar can result in puckers and folds in the perilobular area.
- Shortening the scar compromises access to deep layers of the face.
- Skin flaps cannot be shifted in the biogeometrically correct fashion that is of most benefit to the patient.
- The scar is shifted from a concealed area behind the ear to visible area in front of the temple hairline.
- A visible scar may not actually be shorter than that in a long-scar procedure.

Planning the Submental Incision

Most face-lift patients require modification and repair of the neck and submental regions that can only be performed through a submental incision, and optimal improvement in the neck generally cannot be obtained unless a submental incision is made. Traditionally, this incision is placed directly in and along the submental crease in a well-intended but counterproductive attempt to conceal the resulting scar.

Traditional but *incorrect* plan for the submental incision. The incision should not be placed directly along the submental crease (*arrow*), because this will reinforce the submental retaining ligaments and accentuate the double-chin appearance. The typical plan of skin undermining (*yellow area*) also promotes a double-chin appearance, because the crease is not undermined, retaining ligaments are not released, and the fat of the chin and neck cannot be readily sculpted to create a smooth transition between them.

This incision plan should be avoided, however, because it will surgically reinforce the crease and accentuate a double-chin or witch's-chin deformity. Exposure of the submental region will also be compromised, and the surgeon will encounter difficulty when suturing or dissecting low in the neck. A more posterior placement of this incision will eliminate these problems but will still result in an inconspicuous and well-concealed scar.

Correct location for the submental incision. Placing the submental incision 1.5 cm posterior to the submental crease prevents accentuation of the "double chin" and witch's chin deformities and provides for easier dissection and suturing in the anterior neck (compare with the illustration above). This incision plan allows the submental crease to be undermined and submental retaining ligaments to be released, and the fat of the chin pad and neck can be sculpted to create a smooth transition between them (see p. 1550, *top*).

Correction of the double-chin deformity. *Left*, This patient, seen preoperatively, had a double chin. *Right*, The patient is shown after a face and neck lift. The submental incision was made posterior to the submental crease to allow undermining and release on the submental retaining ligaments and blending of chin and neck fat.

The submental incision should be placed well within the mandibular shadow and well posterior but parallel to the submental crease at a point lying roughly half the distance between the mentum and hyoid. This usually corresponds to a site 1 to 2 cm posterior to the crease.

Plan for a submental incision. The submental portion of the face-lift incision (*solid line*) should be placed well within the mandibular shadow and well posterior but parallel to the submental crease (*dotted line*), approximately half the distance between the mentum and hyoid (*arrows*). Usually this corresponds to a point about 1 to 2 cm posterior to the submental crease.

The incision should be approximately 3 to 3.5 cm in length but may be made longer if necessary, as long as neither end will be advanced up on a visible portion of the face when skin flaps are shifted. Healing will be best, and the scar will be best concealed, if it is made as a straight, not curved, line.

Healed submental incisions. Placement of the submental incision posterior to the submental crease will still result in an inconspicuous, well-concealed scar (*arrows*) as well as provide better access and exposure when working in the deep layers of the neck. The incision location is the same for a male or a female patient. *Left*, Close-up view of a healed submental scar in a female patient. *Right*, Close-up view of a healed submental scar in a male patient.

Planning Modification of the SMAS and Platysma

All patients undergoing a face lift will benefit from posterior-superior advancement of the cheek SMAS; this maneuver is the fundamental step in a natural-appearing, attractive rejuvenation of the face on which all others are based.

High SMAS flap. *Left*, Plan for a basic high SMAS flap. The superior margin of the flap is planned at the level of the zygomatic arch, not inferior to it. *Right*, High SMAS flap after advancement and suturing. Unlike traditional low SMAS procedures, the superior margin of the flap is suspended above the zygomatic arch to the innominate deep temporal fascia, and a broad effect across the entire hemiface is obtained that includes the midface, infraorbital, and perioral regions.

SMAS advancement provides a natural-appearing and long-lasting correction in the cheek and jaw and will strengthen, secure, stabilize, and reinforce the lower face. A high SMAS plan can be used to improve the midface and infraorbital and perioral areas without the need for a separate midface lift. For some patients, a simple SMAS flap advancement alone will provide appropriate correction. Others, however, will require additional maneuvers or modifications of this step to adequately address their problems.

Assessment of the Cervicosubmental Region

Each patient's cervicosubmental region must be carefully examined both at rest and during platysma activation to completely assess platysma deformity. The surgeon asks the patient to "push your jaw forward and tighten your neck," demonstrating this maneuver first so the patient can perform it correctly. Frequently an insignificant-appearing deformity at rest will be obvious when the muscles are clenched. Failure to recognize and appropriately correct these *dynamic deformities* is the reason too many face-lift patients appear improved in repose but unnatural or bizarre during conversation, animation, and other activities that require activation of the platysma muscle.

Dynamic assessment of the cervicosubmental region. The neck is examined as the platysma is contracted. Dynamic platysma muscle irregularities are often called *platysma bands*.

Examination of the cervicosubmental region with and without platysma activation allows one to distinguish between "soft" and "hard" cervical bands. Soft bands change little during platysma activation and are predominantly a problem of skin laxity. Hard bands are tight or become exaggerated when the platysma muscle is activated, indicating a problem of platysmal origin.

It is important to distinguish between soft and hard platysma bands, because treatment will vary, depending on the type of bands present. Patients with hard bands require a *transverse platysma myotomy*. The result of a platysma myotomy is immediate, dramatic, long-lasting, and superior to any suture, suture suspension, or corset technique. The length of the transection required will vary, depending on the configuration of bands present, and will thus differ from patient to patient. However, patients with soft bands can usually be adequately treated with skin excision, skin excision plus platysmaplasty (suturing of the medial muscle borders together, or lateral platysmapexy alone; see p. 1554).

Platysma bands generally lie in medial and lateral locations. Each band is situated near the medial and lateral platysma muscle borders but does not usually correlate precisely with them. For patients with anterior platysma bands only, a transverse platysma myotomy is planned from jugular vein to jugular vein at the level of the cricoid cartilage. The muscles need not be completely transected under these circumstances; just the region where the platysma band is present.

Plan for treatment of anterior platysma bands. Transverse platysma myotomy is performed in the region of the platysma muscle where the platysma band is present. *Left*, The anterior neck is illustrated after a platysmaplasty but before an anterior platysma myotomy. *Right*, After an anterior platysma myotomy at the level of the cricoid cartilage. (NOTE: Myotomy is most easily and effectively performed after the platysmaplasty has been completed.) Dividing the platysma at the level of the cricoid keeps the incision in an area where the muscle is thin and is less likely to bleed and show. Dividing the platysma in the cervicomental angle will result in an unnatural, harsh transition from the submental region to the neck and can cause lower lip dysfunction.

If lateral as well as anterior bands are present, the myotomy is carried more laterally to include them as well. If definition is poor over the lateral mandibular border, in addition to anterior and lateral neck bands, platysma myotomy is planned to continue full-width superolaterally up to the anterior border of the sternocleidomastoid muscle to join the incision in the SMAS. A similar full-width myotomy of this type is also indicated in an individual with a firm, obtuse neck with a short platysma and poor definition over the mandibular angle, but no bands.

In many necks, only a subtotal myotomy need be performed. As a practical matter, however, complete transection of the platysma is performed in most patients to ensure the best contour possible and to limit the potential of band recurrence or that residual platysma bands will be present. Despite assertions to the contrary, a full-width platysma myotomy will not result in a neck that appears to thin or reduced support of the submandibular glands. *Medial wedge resections of platysma at the hyoid and vertical excisions of platysma bands are not effective and usually result in secondary deformities.* These procedures are not recommended, and experience has shown that they should not be performed.

Plan for treatment of anterior and lateral platysma bands. If lateral bands are present, the myotomy is carried more laterally to include them. *Left*, The anterior neck is illustrated after a platysmaplasty but before an anterolateral platysma myotomy. *Right*, After an anterolateral myotomy at the level of the cricoid cartilage. (NOTE: Myotomy is most easily and effectively performed after the platysmaplasty has been completed.)

Plan for full-width platysma transection. A full-width myotomy corrects not only anterior and lateral bands, but also provides improved definition over the lateral mandibular border. *Left*, The anterior neck is illustrated after a platysmaplasty but before a full-width platysma myotomy. *Right*, After a full-width platysma myotomy at the level of the cricoid cartilage. (NOTE: Myotomy is most easily and effectively performed after the platysmaplasty has been completed.)

If submental support is poor and/or optimal improvement in the anterior neck is desired, *anterior platysmaplasty* is planned. Anterior platysmaplasty helps consolidate the neck and optimizes improvement in neck contour but is *not* adequate or effective in the treatment of platysma bands.

Anterior platysmaplasty. Repair of platysma diastasis improves submental support and helps consolidate the neck. However, it is *not* an adequate or effective treatment of platysma bands.

When mild horizontal platysma muscle redundancy is present in the neck, a *lateral platysmapexy* is planned. A lateral platysmapexy ensures that the platysma is draped smoothly and snugly along the cervicomental angle and helps to further improve and consolidate the neck, especially when the patient looks down. It is usually effective only when suturing is performed in the firm, dense tissue in the perilobular areas and over the upper fourth of the sternocleidomastoid muscle, where its fascia is immobile. In thin necks, the cut muscle edges can be overlapped. In fuller necks, redundant muscle can be trimmed and the muscle segments sutured edge-to-edge.

Lateral platysmapexy. *Left*, Before a lateral platysmapexy. *Right*, After a lateral platysmapexy. The lower lateral border of the SMAS flap is sutured to the dense fascia in the perilobular area and over the upper sternocleidomastoid muscle. (NOTE: The lateral platysmapexy should be performed *after* the anterior platysmaplasty.)

When a patient's horizontal platysma muscle redundancy is large or optimal improvement in cervicomental contour is desired, a *postauricular transposition flap* of cheek SMAS is planned. The postauricular transposition flap is created by splitting off redundant tissue from the posterior margin of the cheek SMAS flap, but leaving it attached inferiorly to the cervicosubmental platysma. If properly constructed and secured, this flap will provide dynamic reinforcement of the upper neck and submental areas when the patient looks down. When used in conjunction with an anterior platysmaplasty, postauricular transposition flaps result in a continuous mastoid-to-mastoid sling of muscle across the upper neck along the cervicomental angle.

From a practical standpoint, the final decision about how to manage horizontal platysma redundancy and whether platysmapexy or postauricular transposition flaps should be used is best deferred until the day of surgery, when the effects of SMAS advancement and anterior platysmaplasty can be determined.

Plan for postauricular transposition flap. *Top*, Plan for postauricular transposition flap. *Bottom left*, Elevation and transposition of flap to postauricular area. *Bottom right*, After SMAS elevation and suturing. To be effective and produce the best accentuation of the jawline, the flap must be fashioned so that it pulls posteriorly on the cervical platysma below the mandibular border, not on the lower cheek SMAS above it. (NOTE: From a technical standpoint, it is best to raise the entire SMAS flap and suspend it by its superior margin first. The postauricular transposition flap can then most easily be separated from its posterior margin.)

Planning the Modification of the Submental Region

Traditional face-lift techniques do not adequately address many aspects of aging in the submental region, and *it is not enough in most situations to limit treatment of the neck to preplatysmal lipectomy and postauricular skin excision*. For many patients subplatysmal fat accumulation, submandibular salivary gland “ptosis,” and digastric muscle hypertrophy will contribute significantly to their neck deformity, necessitating additional treatment.

In many patients a significant portion of cervical fat accumulation will be present in a *subplatysmal* location, and little if any fat will need to be removed from the preplatysmal layer. Indeed, as patients age, fat stores generally shift from preplatysmal to subplatysmal, and the small amount of subcutaneous fat present in a typical patient presenting for a face lift is necessary and must be preserved to maintain a soft, youthful, attractive appearance.

Abnormal collections of subplatysmal fat can be identified by preoperative palpation of the neck with and without platysma activation. Fat lying predominantly in a preplatysmal position will generally feel soft and will remain in the examiner’s grasp when the platysma muscle is activated. Fat lying in a subplatysmal position, however, will have a firmer feel, and will tend to be pulled superiorly out of the examiner’s grasp when the platysma is contracted.

Assessing the location of cervicosubmental fat. *Left*, The patient’s submental “wattle” is grasped with the face and neck in repose. *Right*, The patient is then asked to activate the platysma muscle. In this example, the fat is pulled superiorly from the examiner’s grasp, indicating a predominantly subplatysmal position. Fat lying predominantly in a subcutaneous, preplatysmal position would tend to remain within the examiner’s grasp when the platysma is contracted.

Subplatysmal fat accumulations are typically present in patients with firm, obtuse necks who have had lifelong cervicomental fullness. In these individuals, partial *sub*-platysmal lipectomy will be productive, but complete removal of all subplatysmal fat is rarely indicated. The final decision about performing a subplatysmal lipectomy is best made after the subplatysmal space has been explored.

The submandibular glands must be assessed preoperatively because they often contribute to the appearance of a full, “lumpy” neck. Large submandibular glands are most easily seen in a secondary face-lift patient who has had a prior aggressive cervicosubmental lipectomy. Large glands are frequently hidden by submental fat or a lax platysma muscle in a patient with a full neck presenting for a primary procedure, and a plan that does not recognize this fact will lead to disappointing and unexpected bulges in the lateral submental regions postoperatively.

Prominent submandibular glands. Submandibular glands are usually evident as protruding masses in the lateral submental triangle, lateral to the anterior belly of the ipsilateral digastric muscle and mandibular border. *Left*, This patient had residual prominent submandibular glands after a face lift with submental liposuction. His prior procedure made the prominent glands more obvious. *Right*, This patient had residual prominent submandibular glands after a “weekend neck lift.” Aggressive resection of subcutaneous fat had exposed the prominent gland.

Submandibular glands are usually palpable as firm, smooth, discrete, mobile masses in the lateral submental triangle, lateral to the anterior belly of the digastric muscle and medial to the inner aspect of the ipsilateral mandibular border. Submandibular glands lying deep to the plane tangent to the inferior border of the mandible and the ipsilateral anterior belly of the digastric muscle do *not* disrupt neck contour and will usually *not* require treatment. However, glands protruding *inferior* to this plane are likely to be problematic if excess cervical fat is removed and redundant skin is excised.

Despite some claims to the contrary, experience has shown that prominent submandibular glands are actually large, not ptotic, and that the platysma contributes little to their position or support. Attempts at tightening the platysma when a promi-

ment gland is present usually results in a modest, short-lived improvement. Careful sculpting of the periglandular fat will sometimes disguise small glands, but for large, prominent glands, the protruding portion must be resected to achieve a sustained, optimal improvement.

The decision to perform submandibular gland resection should be made in conjunction with the patient after appropriate discussion of the advantages and disadvantages of the procedure. Patients should know that the procedure may prolong submental induration and edema and carries a small theoretical (but unlikely) risk of bleeding, sialoma, salivary fistula, and dry-mouth symptoms.

A small subgroup of patients will have digastric muscles with large, bulky anterior bellies that are evident as linear paramedian submental fullness. Large anterior bellies of the digastric muscles are most easily seen in a secondary face-lift patient who has had prior aggressive cervicosubmental lipectomy. As in the case with large submandibular glands, large digastric muscles are frequently hidden by excess submental fat or lax platysma muscle in a patient presenting for primary procedures, and failure to identify them may lead to unexpected and objectionable submental bulges postoperatively. In these individuals, subtotal *superficial digastric myectomy* should be considered. The final decision to perform partial digastric muscle resection is best deferred until the day of surgery, when the improvements produced by other modifications of the submental region can be evaluated.

Preoperative Preparations

All patients undergo a preoperative physical evaluation, and any with significant medical problems must be cleared by their internist or personal physician before their procedure is performed. Patients are required to avoid agents known to cause platelet dysfunction for 2 weeks before surgery; they are given a list of products such as aspirin, ibuprofen, ketoprofen, naproxen, nonsteroidal antiinflammatory drugs, vitamin E, and other prohibited products.

Patients who smoke are asked to quit 4 weeks before their procedure and are required to avoid smoking and all secondhand smoke for 2 weeks after surgery. Patients who smoke or have a significant history of smoking but have quit are advised in writing that their risk of serious complications, including poor healing, flap necrosis, skin slough, and thromboembolic phenomena, is significantly higher than in non-smokers. It is generally assumed, however, that most patients will not cease smoking, and extra care should be taken to ensure that informed consent is complete in this regard. Fortunately, flap viability depends on a variety of factors other than smoking that are under the surgeon's control or are minimized by the high SMAS procedure design. These factors include tissue trauma, the extent of skin undermin-

ing, and the amount of skin tension. Because the high SMAS technique limits skin undermining, preserves important cheek perforators, and avoids tension on delicate cervicofacial skin flaps, a careful surgeon employing proper technique can operate safely on smokers. Indeed, some surgeons allow patients who smoke to do so in the perioperative period and have observed no increase in complications. *Smokers should always be approached with caution, however, and every surgeon should recognize that these patients are at high risk for serious local and systemic complications.*

All patients are instructed not to color their hair, have a permanent, or otherwise chemically treat their hair during the 2-week period before and after surgery, because this may result in hair breakage and loss. Patients are instructed to shower and shampoo with antiseptic soaps the night before surgery, paying careful attention to the periauricular areas.

It is important that adequate operating room time be allotted for contemporary face-lift procedures, since they are deceptively time consuming compared with traditional or more limited techniques. A high SMAS face lift, when performed in conjunction with a foreheadplasty, eyelid surgery, fat injections, dermabrasion, and other procedures, may often encompass 6 to 8 hours or more, even when performed by a “fast” surgeon working with a well-organized and experienced operating room team. Most surgeons I know who regularly perform these complicated combined procedures have resigned themselves to this fact and have made appropriate adjustments in their surgery schedules. Usually this means allotting an entire day for the procedure. For difficult procedures, or when additional surgery is requested (such as rhinoplasty), it is recommended that the procedures be staged over two separate (consecutive or nonconsecutive) days.

It is strongly recommended that any surgeon new to these techniques consider staging a full-face rejuvenation over 2 days. This worked well for me early in my practice and is still recommended for certain patients with difficult or unusual problems and those who request multiple ancillary procedures. Typically, face and neck lifts are performed the first day. The patient is then usually returned to the operating room the following day or a few days later for foreheadplasty, blepharoplasty, and other procedures. Patient acceptance of this recommendation will be high if it is presented to them as being in their best interest and that it is part of the surgeon’s efforts to ensure their safety and provide high-quality care.

Anesthesia

The majority of face lifts I perform are now done with the patient under deep sedation administered by an anesthesiologist using a laryngeal mask airway (LMA). A laryngeal mask technique allows the patient to be heavily sedated without com-

promise of their airway, but the patient need not be given muscle relaxants and can be allowed to breathe spontaneously. A laryngeal mask is also less likely to become dislodged during the procedure than an endotracheal tube, and it is less likely to trigger coughing and bucking when the patient emerges from the anesthetic. However, any skillfully administered anesthetic is adequate for performing the procedure.

Most modern, comprehensive face-lift techniques, including the high SMAS procedure, are time consuming, technically demanding, and will test the patience and composure of the surgeon. It is highly recommended that any surgeon new to these techniques enlist the services of an anesthesiologist or competent CRNA. This is particularly important when the procedure is to be performed on a patient who is apprehensive, has a history of difficulties with anesthesia, hypertension, or other significant medical problems. This will avert the frustration and stress of trying to master a technically demanding procedure while bearing the responsibility of supervising the administration of an anesthetic, monitoring the patient, and managing intraoperative problems.

Most patients receive preoperative medication tailored and adjusted to their age, weight, height, personality, specific circumstances, and general health; this regimen is modified depending on the type of anesthetic used. *Oral narcotics should not be given as part of the premedication, because they commonly result in nausea and vomiting.* Cocaine, anticholinergics, and parasympathomimetics are also avoided.

We administer antiemetics preemptively at the beginning of each procedure, and patients with a history of perioperative nausea are usually given several agents to block the emetic reflex at multiple levels. All patients are fully monitored with electrocardiography, automatic sphygmomanometry, transcutaneous pulse oximetry, and mainstream capnography. Perioperative blood pressure is closely monitored and fluctuations are aggressively treated, especially in patients with existing hypertension or a borderline condition. The latter group of patients should be watched closely and treated preemptively, because they typically become hypertensive once the surgery and anesthesia is begun.

Surgical Technique

The patient is placed supine on a well-padded operating table, with a special effort to ensure that the elbows, heels, and other potential pressure points are well protected. The patient's lower extremities are elevated and antiembolic pedal compression devices applied. An indwelling balloon-tipped urinary catheter is placed after sedation is begun or general anesthesia administered. A temperature probe is taped in the axilla or groin, and the patient is sufficiently covered or a patient-warming

device is applied to allow the room to be cooled for the comfort of the scrubbed team members.

Each patient receives a full surgical scrub of the entire scalp, face, ears, nose, neck, shoulders, and upper chest with full-strength (1:750) benzalkonium chloride (Zephiran) solution the day of surgery after a bland ophthalmic ointment is instilled in each eye. The patient's head is then placed through the opening of an adhesive-backed disposable transverse laparotomy sheet, leaving the entire head and neck region unobscured from the clavicles up. This allows unimpaired examination of the cervical profile in its entirety throughout the procedure and provides complete access to all areas of the scalp. No head drapes are used, because they will limit scalp access and make it difficult to determine hair shaft inclination and make incisions properly.

The breathing circuit is draped separately from the patient by wrapping it with a sterile sheet or covering it with a sterile stockinette. This allows it to move during the procedure as the patient's head is turned from side to side. When set up in this manner, it is not necessary to secure the LMA with tape or by other means, as long as its position is watched by the anesthesiologist and/or other members of the operating room team present. If an endotracheal tube is used, it can be conveniently secured to the perioral skin with Tegaderm or similar sterile, adhesive-backed dressing.

After the general preparation of the face is complete and drapes have been applied, the posterior surface of the tragus and the auditory canals are prepared with full-strength povidone-iodine (Betadine) using cotton-tipped swabs by a scrubbed member of the surgical team. Each nasal vestibule, the perioral area, and the gingivolabial sulci are prepared with povidone-iodine as well. Peanut sponges are placed in each auditory meatus, and these are changed as necessary during the procedure to prevent the accumulation of blood in the auditory canals.

No hair is cut or shaved along any proposed site of incision. Shaving or trimming hair will prevent accurate assessment of hair shaft inclination relative to the scalp and can result in incisions that injure hair follicles. Tightly applied rubber bands, adhesive tape, surgical lubricants, antibiotic ointment, and hair clips produce similar problems and should also be avoided. It is always an error to pre shave any area of the scalp before the procedure, because this commits the surgeon to excision of these areas, even if this is determined to be inappropriate intraoperatively. As a practical matter, in a well-planned face lift, little if any scalp tissue should actually be excised.

Administering Local Anesthesia

A local anesthetic is administered, even if deep sedation or general anesthesia is used. This limits stimulation of the patient and the overall amount of anesthetic needed. A significant hemostatic effect is also obtained when solutions containing epinephrine are used.

Sensory nerve blocks are performed using 0.25% bupivacaine (Marcaine) with epinephrine 1:200,000. This allows the rest of the face to be injected with a reduced degree of stimulation. Skin marked for incision is then infiltrated with the same solution. Areas of subcutaneous dissection are infiltrated with 0.1% lidocaine (Xylocaine) with epinephrine 1:1,000,000 using a 22-gauge spinal needle in the cheek and postauricular areas and a blunt infiltrator in the neck and submental regions. Care is taken to ensure that the total dose of bupivacaine does not exceed 3 mg/kg of body weight and lidocaine does not exceed 7 mg/kg of body weight per 4 hours. *No direct infiltration of the SMAS or platysma is necessary if the overlying subcutaneous tissues are infiltrated generously at the beginning of the procedure, as described.* It is not necessary to inject local anesthetic in a tumescent fashion.

The local block is maintained by systematically reinfusing the key areas (preauricular and postauricular) during the procedure and readministering nerve blocks *before the local anesthetic effect wears off.* This prevents loss of continuity of the local anesthetic effect and stimulation of the patient that would otherwise occur if reinjection were delayed until after sensation returned.

Making Incisions

All incisions on the scalp must be made precisely parallel to the hair follicles to avoid injury to them, and it is important to confirm by direct observation that this is true as the incision is made.

Incising the skin and scalp is a key step in which the surgeon exercises direct control over the quality of the resultant scar, and incisions should not be made casually or carelessly. All incisions on the scalp or along scalp-skin interfaces must be made precisely parallel to the hair follicles to avoid injury to them, which can result in perincisional alopecia. Frequently this is mistakenly attributed to the patient's own poor healing characteristics and is erroneously regarded as "a wide scar."

In most cases, follicles and hair shafts will be similarly inclined, but this may not be true in a kinky-haired or curly-haired individual or when the patient's hair is wet, saturated with surgical lubricants, or restrained with drapes, tape, or rubber bands. For this reason *it is important to confirm by direct observation that the incision is precisely parallel to the hair follicles as it is made.* One must also recognize that hair

follicle inclination is not uniform over the scalp: follicles will be inclined differently at different areas along the planned incision. Because of this, the angle of the scalpel blade with the scalp must change correspondingly as the incision is made, and the completed incision will be beveled to varying degrees and in different directions, if properly performed.

Skin Flap Elevation

After incisions are made, skin flaps are elevated according to the preoperative plan over the cheek and neck. *Partial separation of the skin flap from the SMAS (lamellar dissection) is necessary because skin and SMAS flaps need to be advanced in different direction to achieve an optimal outcome.* This “bidirectional” tissue shift is not possible if a “composite” type of dissection (elevation of a combined skin-SMAS flap) is done.

Correct positioning of the operating room lights and proper retraction by the assistant is essential for proper dissection, and unnecessary trauma to the flaps must be avoided. Light should be placed on both sides of any flap being dissected to provide simultaneous direct and transmitted illumination; blind dissection must be avoided. Shining a light on the skin surface (transillumination) will help define flap thickness, while lighting the site of dissection (direct illumination) allows identification of important structures. However, too much direct illumination can obscure the transillumination effect and must be avoided. This is particularly true of the bright direct light emitted from fiberoptic headlights and retractors. If they are used, their intensity should be reduced to produce proper, balanced illumination.

The circulating nurse or other unscrubbed team member should be assigned the task of adjusting the overhead lights as needed and the importance of this assignment emphasized. In time, a perceptive nurse need only watch the operative field to know when adjustment is needed. If the circulating nurse is required to monitor the patient, administer medication, or frequently leave the operating room, it is recommended that an additional staff member be present for adjusting lighting.

The surgeon and assistant should refrain from adjusting the overhead lights, because each will need both hands free for proper retraction and dissection. *Adjusting the lights with one hand while retracting with the other is a common error that invariably results in excessive traction on the flap and unnecessary trauma to delicate cervicofacial tissue.*

Proper care of the patient and effective functioning of the operating room team requires that two team members be scrubbed with the surgeon throughout most of the procedure. One scrubbed team member will be necessary to act as a full-time surgical assistant. This is a key role that generally precludes passing instruments, loading sutures into needle holders, tracking sharps, and maintaining the instrument

stand. A second scrubbed team member should be present to oversee and carry out these important secondary functions. Regardless of experience or claims to the contrary, it is not possible for one person to effectively assume both roles without compromising her or his role as an assistant and otherwise slowing down the surgical procedure.

Cheek flap dissection is begun using an Adson forceps and a small Kaye scissors or scalpel, grasping only tissue edges that will later be excised. Once the flap edge has been elevated, the forceps are set aside and gentle traction is applied by the assistant with double-pronged skin hooks. A standard patterned medium curved Metzenbaum scissors is then used to establish the proper plane.

Flap dissection is most effectively performed when the surgeon and assistant work together as a carefully coordinated team using a *four-handed technique* in which the assistant applies gentle traction on the skin flap directed toward the surgeon with two large double-pronged skin hooks. One skin hook retractor should be held in each hand, because it is not possible for the assistant to provide proper retraction using a one-handed technique (holding both retractors in one hand). The surgeon then dissects while providing gentle countertraction toward the assistant with the fingertips of the opposite hand.

Four-handed technique. The assistant applies gentle traction on the skin flap toward the surgeon with two large double-pronged skin hooks with one retractor held in each hand. The surgeon then dissects while providing gentle countertraction toward the assistant with the fingertips of the opposite hand.

As the dissection advances, one skin hook is exchanged for a small Deaver, malleable, or similar retractor. The remaining skin hook is used to drape the flap over the retractor and keep it properly positioned on it. This eliminates the need for excessive traction and minimizes trauma to the flap.

The surgeon should not retract for herself or himself, because this invariably leads to rough handling of the flap, especially when exposure is limited or dissection becomes difficult. Retracting should instead always be performed by a conscientious assistant capable of focusing his or her attention on providing proper exposure and protecting delicate facial flaps. This assistant must ignore his or her natural urge to “help” the surgeon by applying excessive force when retracting. It must also be kept in mind that most hospital and surgery center personnel are accustomed to assisting surgeons in other specialties and have not been trained in proper tissue-handling techniques. They are usually not aware that improper retracting, excessive traction, and rough handling of the flap are harmful and can lead to flap compromise, tissue necrosis, and skin slough, and time taken to teach them proper retracting techniques is well spent.

Tissue trauma to skin flaps can be significantly reduced by periodically moving the dissection from one area to another and completing flap elevation in stages. This allows the tissue to “breathe” and avoids prolonged compromise of any one area. Traction should also be released before retractors are moved. If traction is not released, the flap’s microcirculation will be compromised as the retractor is moved from side to side.

All operating room team members should be responsible for ensuring that flaps are handled carefully and that they are not subjected to excessive traction, pinching, folding beneath retractors, or other potentially harmful actions. It is not possible for the surgeon, who is usually preoccupied with other aspects of the procedure, to always be diligent in this regard.

Skin flaps should be elevated sharply under direct vision, avoiding blind dissection. This is especially important in the preauricular region and over the cheek, where a deep dissection can injure and compromise the underlying SMAS or render it useless as a flap. *I have observed that many surgeons using non-SMAS face-lift techniques dissect deeper than they realize*, and inspection of their flaps after dissection often reveals that SMAS fibers have been elevated as part of the “skin” flap. It is also an error to dissect too close to the posterior surface of the skin flap, because this can result in injury to the subdermal microcirculation.

Although subtle, some visual clues are helpful in avoiding these problems and determining when the proper plane has been established. If skin flap dissection is made too deep and SMAS fibers are elevated, the flap’s undersurface will appear relatively smooth and covered by streaks of fine white tissue. When transilluminated, flaps dissected in this manner will appear cloudy and relatively thick. If dissection is made in the proper plane, however, the undersurface of the flap will have a characteristic

rough pebbled or cobblestone appearance and will be more yellow. Transillumination of a flap dissected in the correct plane enhances this appearance.

Blind dissection done by pushing scissors or blunt dissection using a scissors-spreading technique is unacceptably traumatic to the subdermal microcirculation of the skin and can result in flap compromise, damage to subdermal fat, and unintended injury to the SMAS and platysma. This is particularly likely when aggressively patterned, doubled-edged, serrated, and extra-sharp scissors are used. After experimenting with many scissors patterns, I have found none as good as the standard Metzenbaum type.

Postauricular skin flap undermining is most easily begun inferiorly if the occipital incision has been made along the occipital hairline, or posteriorly if the incision has been made over the occipital scalp, because more subcutaneous fat is usually present in these areas. Beginning dissection in these areas helps the surgeon identify the proper plane more superiorly and anteriorly in the postauricular area, where less subcutaneous fat is present and the skin and fascia lie in close proximity. Careful infiltration of dilute local anesthetic into the plane of dissection also facilitates dissection in these areas, but large-volume tumescent injections should be avoided, because these can injure delicate postauricular skin.

Once the correct plane of dissection has been established in the postauricular area, two 10 mm double-pronged skin hook retractors are placed and held by the assistant, and Metzenbaum scissors are used to elevate the postauricular skin flap. Postauricular flap elevation should be done under direct vision aided by transillumination. Dissection is most easily performed in a posterior-to-anterior direction rather than in a superior-to-inferior one.

As dissection progresses anteriorly and inferiorly from the postauricular region to the upper lateral neck, the surgeon must be careful to avoid injury to the great auricular nerve. This nerve provides sensation to the lower two thirds of the ear and travels superficially superiorly in the upper lateral neck over the sternocleidomastoid muscle fascia. The most superficial portion of the nerve is anatomically constant, lying approximately 6.5 cm inferior to the auditory meatus midway between the anterior and posterior borders of the sternocleidomastoid muscle. In most patients, however, it will lie deep to the plane of skin flap dissection and is covered by a thin layer of subcutaneous fat. In these cases, it is neither necessary nor advisable to attempt to specifically identify or isolate this nerve through additional dissection.

Patients with thin faces or those undergoing secondary face lifts will not uncommonly have little subcutaneous fat between the superficially situated portion of the great auricular nerve and the skin. For this reason, extra caution must be taken in these patients when elevating the skin flap in this area, and a clear knowledge of nerve anatomy is required.

As dissection continues anteriorly into the cervical region, subcutaneous fat generally becomes more abundant, and the flap is easier to dissect. The surgeon must be careful to remain in a subcutaneous plane and to leave the majority of the preplatysmal fat on the platysmal surface. This makes fat excision and sculpting easier later in the procedure, if required, and precludes the need for tedious excision of fat from the undersurface of the cervical skin flap. Unlike dissection of a cheek skin flap, in which a conscious effort must be made to prevent the flap from becoming too thick, a slightly deeper dissection should be made in the neck to preserve a slightly thicker layer of subcutaneous fat. Preserving a thicker layer of fat helps to avoid a hard or overresected appearance in the cervicosubmental area and objectionable overexposure of underlying neck anatomy.

If a submental incision is planned, completing subcutaneous dissection of the anterior neck skin flap will be more easily performed through it, rather than through the postauricular incisions. Undermining the submental crease and releasing the submental and mandibular ligaments will also be easier when performed through the submental incision.

The submental incision should be made 1 cm or more posterior to the submental crease, approximately halfway between the mentum and hyoid. Placing the incision in this location helps conceal it in the shadow of the mandible and avoids surgical reinforcement of the crease and accentuation of a double-chin and witch's-chin deformity. The surgeon should stand at the head of the table during dissection of the submental region while the assistant retracts the edges of the submental incision with a pair of 10 mm double-pronged skin hooks. The skin is undermined using Metzenbaum scissors, and the dissection should be made subcutaneously, leaving the majority of the preplatysmal fat on the platysma surface. Submental dissection is continued inferiorly and laterally until it is joined with the dissection made previously in the lateral neck.

On completion of subcutaneous undermining of the anterior neck and submental regions, the submental restraining ligaments should be divided and the submental crease released from its bony attachments. Some bleeding is usually encountered during this maneuver, but this should not prevent the surgeon from completing this important step.

Although in most patients' necks subcutaneous undermining is necessary, this should not arbitrarily include the entire face. If a SMAS dissection is planned, preservation of the anterior platysma-cutaneous ligaments will allow attractive, youthful-appearing elevation of perioral tissue that cannot be obtained with a skin-only technique or when wide skin undermining is performed.

Extent of subcutaneous undermining. The shading indicates the area of subcutaneous undermining. Note that the platysma-cutaneous ligaments (*red dots*) are not undermined and are preserved. Preservation of platysma-cutaneous ligaments and proper elevation and fixation of the SMAS provides support of lateral perioral tissues and prevents the "lateral sweep" deformity.

These ligaments anchor the dermis of the perioral cheek to the SMAS and upper platysma and provide a means of lifting and supporting the lateral perioral area without overtightening the skin of the upper-lateral face. Preservation of the platysma cutaneous ligaments also preserves important accompanying perforating vessels to the cheek flap. This reduces the likelihood of flap slough, swelling, and compromise.

If subcutaneous dissection is extended too far anteriorly and the platysma-cutaneous ligaments are divided, the SMAS effect on the superficial tissues of the perioral cheek and jowl will be negated, and a significant portion of the benefit of SMAS elevation and advancement will be lost. Wide cheek flap undermining and division of the platysma-cutaneous ligaments is also the underlying cause of the lateral sweep deformity, since SMAS support of sagging perioral tissues is lost when dissection is performed in this manner.

Temple Dissection

The temple incision is made according to the preoperative plan based on the redundancy present over the upper cheek and the predicted degree of displacement of the sideburn and temporal hairline (see the preceding section).

When a traditional incision on the temporal scalp is indicated, it is made precisely parallel to hair follicles. This will generally require that the incision be beveled to varying degrees and in different directions along its length. The dissection is then deepened and carried down through the galea (superficial temporal fascia) to the fascia of the temporalis muscle and the temporal hair-bearing fasciocutaneous flap anterior to the incision undermined. This dissection is usually easy to perform bluntly with closed Metzenbaum scissors anteriorly to the lateral brow, inferiorly to the mid-temple, and superiorly to the temporal crest. The bridge of fascia lying inferiorly between the deep dissection in the temple and the subcutaneous dissection in the cheek can be safely and conveniently partially divided posterior to the temporal hairline.

Dividing the mesotemporalis. The bridge of tissue situated between the subfascial (subgaleal) dissection in the temple and the subcutaneous dissection in the cheek can safely be divided posterior to the course of the frontal branch of the facial nerve (*black dotted line*).

Usually this bridge of tissue contains the anterior branch of the superficial temporal artery and it must be divided and ligated when encountered, or thoroughly cauterized. This is of no clinical consequence in a nonsmoking patient who has no vascular disease and is a routine part of the dissection of this area. The frontal branch of the facial nerve lies well anterior and inferior to this chosen point of transition between planes, and this dissection, when executed as described, is anatomically sound and clinically safe. Frontal branch anatomy can be confusing, however, and *a surgeon who is uncertain of the exact relationships in this region should review them carefully before undertaking this dissection.*

Partially dividing the bridge of tissue between the deep plane of the temple and the subcutaneous plane of the cheek allows the two planes of dissection to be joined laterally; this in turn facilitates exposure in the upper cheek and lateral orbit, dissection of the SMAS, and redraping of the temporal portion of the face-lift flap. This method of dissection also protects hair follicles on the undermined temporal scalp by moving the plane of dissection deep to them. Temporal skin can then be undermined subcutaneously up to the lateral orbit, bringing the dissections in the cheek and temple into wide continuity.

When an incision along the temporal portion of the anterior hairline is indicated, it is made a few millimeters within it with a slight bevel, or parallel to the hair follicles. This incision should be made no higher than the junction of the temporal hairline with the frontotemporal hairline; if it is carried more superiorly, the resulting scar will usually be visible, since hair tends to grow posteriorly in this area.

After the incision is made along the hairline, the temporal skin flap is carefully undermined subcutaneously and joined with the subcutaneous dissection in the cheek. No transition between planes is necessary under these circumstances, and no hair-bearing flaps are raised; the superficial temporal vessels and frontal branch of the facial nerve are left undisturbed beneath the superficial temporal fascia.

Flap dissection with a hairline incision. When an incision along the temporal hairline is used, all dissection will be in a subcutaneous plane and no transition between planes will be necessary, no hair-bearing flaps are raised, and the superficial temporal vessels are left undisturbed beneath the superficial temporal fascia.

SMAS Dissection

Once the skin flaps have been elevated, they are retracted and the zygomatic arch is palpated. A line is then traced high over its midportion with water-soluble surgical ink (methylene blue) from the infraorbital rim to a point approximately 1 cm anterior to the superior portion of the tragus. This line lies higher than the dissection made in most other techniques, and well above the malar origin of the zygomaticus major muscle. The mark is then turned inferiorly and carried over the preauricular portion of the parotid 1 to 2 cm anterior to the ear. Inferior to the lobule, it is carried inferiorly and posteriorly to the anterior border of the sternocleidomastoid muscle.

Plan for high SMAS flap. The superior margin of flap is planned over the zygomatic arch and not below it. The frontal branch of the facial nerve (*yellow dotted line*) lies safely posterior and deep to the majority of the dissection.

A basic high flap of this type is used on most patients. There are several important advantages in its design worth considering. First, *planning the superior margin of the flap over and along the zygomatic arch, rather than inferior to it, expands the effect of the flap to include the upper midface and allows a better vector to be applied to it.* Carrying the incision posteriorly and inferiorly over the tail of the parotid to the anterior border of the sternocleidomastoid muscle in the upper-lateral neck also maintains a safety zone between the incision and the mandibular margin and moves the dissection away from the marginal mandibular nerve. Placing the remaining portion of the incision along the anterior border of the sternocleidomastoid muscle places the dissection in a relatively thin and avascular area of platysma and along a line where the cut edge, if visible through the skin after surgery, would appear to be the muscle border.

Plan for high SMAS flap. The marginal mandibular branch of the facial nerve (*black dotted line*) emerges from the anterior border of the parotid gland well anterior to the SMAS incision in the preauricular region. The mark for the posterior incision curves posteriorly to the anterior border of the sternocleidomastoid muscle.

Flap elevation is begun by incising the SMAS over the zygomatic arch. This is accomplished by grasping the preauricular tissue overlying the lateral arch with an Allis clamp on each side of the marked line and having the surgical assistant apply gentle posterior traction on them to tense the SMAS layer. The surgeon then makes an incision with Metzenbaum scissors and continues it medially 1 to 2 cm along the marked line in the tensed plane. Allis clamps are then released and reapplied incrementally as the dissection proceeds farther medially along the marked line in the tensed plane in 1 to 2 cm segments in a similar fashion. A considerable amount of tissue lies over the arch, and the frontal branch will be safely concealed beneath several millimeters of fibrous fat. *The margin for error may be reduced in a thin, aged patient with advanced facial atrophy and less soft tissue cover over the arch or in a secondary procedure; therefore extra caution must be exercised under such circumstances.*

The preauricular limb of the SMAS incision is then made using a similar technique over the posterior parotid along the marked line in the preauricular region. It is continued inferiorly and posteriorly to the anterior border of the sternocleidomastoid muscle. These two incisions define the high SMAS flap to be elevated.

After initial SMAS incisions have been completed, preauricular tissue comprising the posterior-superior corner of the SMAS flap is grasped with Allis clamps and flap elevation is then begun using careful scissors technique. Undermining should be limited in the preparotid cheek, more extensive over the zygoma and upper midface.

Approximate extent of SMAS undermining. Complete release of the SMAS flap will require that both the zygomatic ligaments (*blue squares*) and the parotidomasseteric ligaments (*red dots*) be released.

The SMAS, although substantial, is thinner than many surgeons imagine it to be, and it is decidedly thinner and less substantial than other tissue layers that are typically dissected in plastic surgery procedures. SMAS flap elevation also entails dissection in the plane of the facial nerve, in close proximity to important motor branches. Although flap elevation over the parotid is safe, great care must be taken when dissecting more medially and over the zygomatic arch.

Sharp scissors dissection of the high SMAS flap is usually required posteriorly over the parotid, where the plane between parotid fascia and SMAS is often indistinct. In some instances a portion of the parotid fascia may be incidentally and/or unavoidably raised with the SMAS flap, and part of the lobular surface of the gland may be exposed. This is of no clinical consequence and should be used by the surgeon as an aid in identifying the proper plane of dissection, situated slightly more superficially.

A separate and distinct plane does exist medial to the parotid between the SMAS-platysma and the parotidomasseteric fascia. This plane is most easily identified and established in the lower cheek, where it can usually be entered by gentle blunt dissection with scissors tips, a fingertip, or with a Kitner (peanut) sponge. The parotidomasseteric fascia will be seen as a thin, shiny, transparent layer covering the masseter muscle, parotid duct, buccal fat, and the branches of the facial nerve. Blunt dissection on top of this layer is safe and will not result in nerve injury, but great caution must be exercised when dissecting sharply or when clamping or coagulating in this area. *Frequently motor nerve branches accompany perforating vessels,*

and each bleeding point must be carefully identified when ensuring hemostasis. Blind clamping should not be performed, and a low coagulation current should always be used. The patient's face should also be carefully watched during cauterization and the current discontinued immediately if facial twitching is noted.

Sub-SMAS dissection must generally be carried over the anterior border of the parotid in the lower cheek to ensure that *parotidomasseteric ligaments* tethering the SMAS are released. These are most easily identified by fingertip palpation along the front of dissection. If these restraining attachments are not released, the SMAS effect in the lower cheek and jawl will not be optimal, and the overall benefit will be minimal.

As SMAS flap dissection is made anteriorly and medially in the upper cheek over the superior portion of the parotid and its accessory lobe, the SMAS will be seen to thin and invest the lip elevators. *At this point the dissection must be taken superficial to the superior portion of the zygomaticus major muscle* and its upper 1 to 2 cm carefully exposed. The zygomatic ligaments will be encountered just at the malar origin of the zygomaticus major muscle. These fibrous connections between the periosteum, SMAS, and skin must be divided and when completely released, produce a dramatic liberation of the flap. The lateralmost ligaments are typically more substantial and generally require sharp dissection and formal transection. The ligaments lying more medially are generally softer and can often be disrupted bluntly with open scissors tips.

Directly inferomedial to the origin of the zygomaticus major muscle and superomedial to the accessory lobe of the parotid and the parotid duct lies the zone of transition between the zygomatic and parotidomasseteric ligaments—and potentially the most dangerous part of the SMAS dissection. Proper liberation and release of the SMAS flap usually requires at least partial division of restraining attachments in this area, but this moves the dissection into very close proximity to the zygomatic branch of the facial nerve.

Completed SMAS flap dissection. Inferior to the origin of the zygomaticus major muscle and superomedial to the accessory lobe of the parotid lies the zone of transition between the zygomatic and masseteric-cutaneous ligaments (*red dots*)—potentially the most dangerous part of the SMAS dissection. Proper liberation and release of the SMAS flap usually requires at least partial division of restraining attachments in this area, but this moves the dissection into very close proximity to the zygomatic branch of the facial nerve.

Although experienced surgeons make this dissection appear easy and often seem to minimize the risk involved, it can be difficult for a less-experienced surgeon to distinguish between nerve branches and ligamentous attachments in this area. Anatomic variations are common in this area, and in some cases nerves will penetrate the deep fascia early and travel directly in a sub-SMAS plane or send a branch over the zygomaticus major to the orbicularis oculi. In these situations, traction on the SMAS flap during dissection can tent up these branches, placing them at even greater risk. *It is highly recommended that any surgeon uncertain of the anatomy of the facial nerve and its variations or the exact relationships in this area review them carefully before undertaking this dissection.*

A safe dissection of the submalar SMAS and proper release of the zygomatic ligaments requires adequate light, an attentive assistant, a well-organized surgical team, a dry field, and patience, caution, and composure on the part of the surgeon. Loupes are very helpful in identifying important anatomic structures, and inexperienced surgeons should consider the use of a disposable battery-operated nerve stimulator to aid in initial dissections. *If the neophyte surgeon is confused or the anatomy seems unclear, it is better to limit dissection until he or she gains additional experience and familiarity with this anatomic region, because no amount of improvement in facial appearance is worth an injury to the facial nerve.*

Dissection of the SMAS flap and release of restraining ligaments is continued until gentle traction on the flap produces motion at the nasal ala, philtrum, and stomal angle, and elevation and compression of infraorbital and lower eyelid tissue. *This traction test clinically confirms adequate flap release and is a more important indicator of a complete dissection than any arbitrary anatomic endpoint.* If flap release is incomplete, residual tethering fibers are identified are carefully divided, and the traction test is repeated. When dissection is complete, the midface and malar pad and attached skin will move freely as part of the high SMAS flap, and tissue advancement into the infraorbital area and compression of the lower eyelid skin will be evident. No separate suturing or dissection of the midface is required.

SMAS Suspension

Once the SMAS flap has been elevated and adequately released, the superior edge of the flap is grasped and shifted variously to determine which direction produces the best effect on the upper midface, cheek, and jawl. In all but the unusual case, this is along a posterior-superior vector parallel to the long axis of the zygomaticus major muscle. *If a vertical or posterior vector is used, the function of the zygomaticus major muscle will be corrupted, and an abnormal appearance during animation may result.*

Proper and improper vector of the SMAS shift. *Left*, The correct shift of the SMAS flap is along the long axis of the zygomaticus major muscle. This allows natural muscle function. If the SMAS is shifted along a posteriorly directed vector (*center*), not along the long axis of the zygomaticus major muscle, the muscle will be pulled off its axis and its function compromised. This can result in deepening of the nasolabial fold and abnormal appearances during animation. *Right*, An analogous problem occurs when a vertical vector is used in a “vertical face lift.”

Management of the superior margin of the SMAS flap and the technique of flap suspension will vary, depending on the problems present and considerations particular to the patient, including sex, race, and his or her overall facial morphology. In most cases no trimming of the superior margin of the flap is performed, because the overlapping tissue segments of the SMAS add volume to and restore lost projection over the zygomatic arch. In these situations the superior edge of the flap is anchored with multiple interrupted sutures of 3-0 Mersilene, well over the zygomatic arch, directly to the deep temporal fascia, superior to the mesotemporalis.

High SMAS flap suspension with a temporal scalp incision. The SMAS flap has been advanced superiorly, the mesotemporalis pushed inferiorly, and the flap secured to the temporalis muscle fascia.

Suspension in this manner is greatly facilitated if the mesotemporalis is gently pushed inferiorly as the sutures are placed. This solidly suspends the midface, upper cheek, and jowl with little if any risk of injury to the frontal branch of the facial nerve. No suturing is needed or should be performed more anteriorly over the zygoma or along the infraorbital rim. These parts of the face are mobile and need to move during animation and for natural expression. Directly suspending the midface along the zygoma or infraorbital rim, especially rigidly, can result in the tissue tethering and dimpling often referred to as a *smile block*. If direct anchoring of the flap to the temporal muscle fascia is not possible, even when the mesotemporalis is pushed inferiorly, suspension can still be made in this manner if the sutures are allowed to bridge the intervening gap.

In patients with wide faces and small mandibles, in many men, and in many patients of Asian or Slavic ancestry, enhancement of the upper cheek and arch obtained by overlapping the SMAS may not be artistically appropriate, necessary, or desired. In such cases the redundant tissue along the superior flap margin can be excised and discarded and the superior flap margin sutured edge to edge to the superior margin of the initial incision made in the SMAS over the zygomatic arch.

When an incision along the temporal hairline is used and temporal dissection is done in a subcutaneous plane, temporal muscle fascia will not be exposed and a mesotemporalis will not be present. The redundant tissue along the superior flap margin can

be excised and discarded, and the superior flap margin sutured edge to edge to the superior margin of the initial incision made in the SMAS over the zygomatic arch. Alternatively, the galea can be incised just inferior to the sideburn to expose the temporalis muscle fascia (*innominate fascia*). The SMAS can then be anchored in a manner analogous to the way in which the mesotemporalis has been divided.

High SMAS flap suspension with a temporal hairline incision. *Top left,* To gain access to the temporalis muscle fascia to suspend the SMAS, the sideburn is retracted and the galea incised. *Top right,* The completed incision of the galea under the sideburn exposes the temporalis muscle fascia. Once incised, a "mesotemporalis" (the transition from the subcutaneous plane of the cheek to the subgaleal plane in the temple) is created. If this is done carefully, the superficial temporal artery can be preserved, although it can be divided and ligated without consequence. This establishes a situation for suspension of the SMAS analogous to that shown on p. 1579. *Bottom left,* The suture has been placed through the corner of the SMAS flap. Note that the mesotemporalis is being pushed inferiorly as the suture is placed. *Bottom right,* Additional sutures have been placed between the superior margin of the SMAS flap and the temporalis muscle fascia, securely anchoring the flap. Although unnecessary, a few sutures have been placed and allowed to bridge anteriorly. Once suspension of the SMAS is complete the sideburn is placed back in a proper anatomic place and anchored down before the skin flap is trimmed and the incisions closed.

Regardless of how the superior margin of the flap is secured, invariably some trimming of the posterior margin of the cheek SMAS flap is subsequently required to allow an edge-to-edge approximation to the SMAS remnant in the preauricular region. Overlapping of the SMAS in the preauricular area is functionally unproductive and artistically inappropriate, because such an arrangement lends no additional support to the anterior face and obliterates the natural preauricular contours and the pretragal hollow.

The posterior margin of the cheek SMAS flap should be trimmed after the superior margin has been suspended over the zygomatic arch. Tissue is excised by placing gentle traction on it and tracing a line in marking ink over the cut edge lying beneath it. The amount of tissue excised will vary depending on the size of the patient's face, the degree of release of the flap, and the chosen vector of advancement. *It is unproductive and an error to place excessive traction on the SMAS in the preauricular region*, and the posterior margin of the flap should be trimmed carefully to avoid overexcision and a tight closure. Posterior traction on the SMAS will result in perioral distortion, a "pulled" look, or other abnormal appearances.

After trimming of the posterior margin of the SMAS flap, the cut edge is approximated to the preauricular remnant with multiple interrupted sutures of 4-0 Mersilene with the knots tied on the deep side. These sutures consolidate the cheek and help support the superior suture line but should not be used to put posterior traction on the SMAS flap.

When the cheek SMAS is sutured, the facial contour should be improved and a faint smile should be evident. Usually elevation of the lid-cheek junction and compression of lower eyelid tissue will also be noted.

To provide additional support in the anterior neck and along the submental region, the excess tissue along the posterior margin of the cheek SMAS flap can be left attached to the cervical-submental platysma and used as a *postauricular transposition flap* (see pp. 1556-1557). This flap improves neck contour by correcting horizontal platysma redundancy and increasing submental support. Frequently this cannot be accomplished by lateral platysmapexy (see p. 1556) alone because of the mobility of the tissues in the upper lateral neck. Suturing the transposed segment of cheek SMAS to the mastoid fascia while leaving it attached to the cervical platysma circumvents this problem and improves the result. In addition, a *dynamic* sling is created that tightens the submental region when the patient looks down. This tightening occurs because the mastoid moves superiorly during neck flexion and away from the anterior neck, pulling the transposed flap and attached tissue with it.

When a postauricular transposition flap is used, it must be carefully designed and its effect thoroughly tested intraoperatively. The SMAS must be incised in such a fashion that the transposition flap exerts its effect on the cervical platysma below the mandibular border, and not more superiorly on the SMAS in the cheek. Flap suspension is also best delayed until after the anterior platysmaplasty is completed (see the next section). A postauricular transposition flap, when used in conjunction with anterior platysmaplasty, creates a mastoid-to-mastoid sling of autologous tissue. This is a more natural and superior maneuver than any attempt to accentuate neck contour by the placement of suspension sutures, alloplastic straps or bands, and similar measures.

Cervical Lipectomy

A cervical lipectomy is a technically demanding and conceptually difficult maneuver that requires patience, perseverance, restraint, and artistic sensitivity. Success or failure in neck rejuvenation will be largely determined by the surgeon's proper or improper handling of neck fat. Other maneuvers commonly performed to improve neck contour, including platysmaplasty (a "corsetlike" tightening of the platysma), platysmapexy (Labbé sutures), placement of submental "hammock"-type suspension sutures, and removal and repositioning of cervical skin, are far less important. Accepting this fact is an essential point of transition in most surgeons' quest to provide their patients with the optimal neck contour they desire.

Cervical fat is present in three distinct anatomic layers: preplatysmal, subplatysmal, and deep cervicosubmuscular (*intradigastric*); understanding this distribution is the key to attractive and successful outcomes in the neck. In almost all cases cervical lipectomy should be limited to the two more superficially situated regions, and in a contemporary neck lift the focus is placed predominantly on fat in the subplatysmal layer. Lipectomy technique is not as important as the contours created, and *it should be the aim of the surgeon to produce a well-contoured and attractive neck, and not simply one devoid of fat.*

Contrary to what is traditionally practiced, preplatysmal cervicosubmental subcutaneous lipectomy should in most cases be performed after shifting and suturing of the SMAS and platysma and excision of subplatysmal fat when indicated, and not at the beginning of the procedure. If preplatysmal lipectomy is performed at the beginning of the procedure, fat will be mistakenly excised from regions of the neck that will be raised onto the face when SMAS flaps are advanced and suspended. This will result in inadvertent creation of harsh or irregular mandibular contours.

Sequencing excision of preplatysmal fat. If preplatysmal fat is excised before the SMAS is elevated, denuded areas that were formerly situated below the jawline will subsequently be advanced onto the lower face. This can result in a harsh mandibular contour. To avoid this problem, preplatysmal fat should be removed, if indicated, after the SMAS flap has been raised. *Left*, Incorrect plan for preplatysmal fat excision (*shaded area*). Fat is excised before the SMAS flap is raised. *Right*, After SMAS elevation, the denuded areas are moved up onto the lower face, resulting in contour irregularities and depressions.

Performing preplatysmal lipectomy at the beginning of the procedure also typically results in erroneous removal of the fat necessary to a soft, youthful, healthy appearance. Typically this overresection of subcutaneous fat will not be evident intraoperatively or for the first few months postoperatively because the error is masked by swelling. Once the swelling has resolved, however, the cervicosubmental region will have an unnatural, unhealthy, elderly, and overresected look.

Subcutaneous cervicosubmental fat should be thought of as the surgeon's "artistic clay"; it is my usual practice to leave this layer untouched in most necks until subplatysmal fat excision and deep-layer work have been performed (submandibular gland reduction, partial digastric muscle myectomy), and all other maneuvers (platysmaplasty and platysmamyotomy) have been completed. Once all other work in the neck is complete and the optimal shape of the foundation of the face has been established, only then is final contouring of the subcutaneous fat carefully and conservatively performed. Contouring preplatysmal cervicofacial fat as the last in the sequence of steps used to improve the neck provides one important last opportunity to optimize facial contour and finesse facial appearance that is lost if this fat is arbitrarily sacrificed at an initial stage of the procedure.

In full necks in which excessive subcutaneous fat deposits can be detected, preplatysmal lipectomy can be performed judiciously with a small suction cannula before needed deep-layer maneuvers are performed if care is taken to avoid injury to the platysma muscles and to leave enough fat behind for final fat contouring later in the procedure. This is an unusual circumstance, however; careful preoperative assessment of the subcutaneous fat layer in the neck of most face-lift patients will show that a paucity of fat is present.

In most cases cervicosubmental subcutaneous fat is removed after all other necessary neck maneuvers have been performed. Fat can be removed in such circumstances using an open suction technique with a one-holed cannula turned toward the platysma. In thinner necks, simple excision is done with a scissors technique, or no fat is removed. Preplatysmal lipectomy is usually easiest in the anterior and lateral neck, where it is needed least, and is more difficult in the submental area and near the mandibular border and chin, where it is needed most. Fat in the latter regions is often firmly adherent to the platysma and is usually difficult to remove with a cannula alone. If preplatysmal lipectomy is performed with a suction cannula, fat should be removed in a medial-to-lateral and inferior-to-superior direction, working through both submental and postauricular incisions to prevent disruption of previously placed sutures suspending the SMAS.

Although proper shift of the cheek SMAS often repositions ptotic jowl fat, partial excision and contouring of this area may be necessary in some patients, particularly those with round, full faces. It is also usually productive to examine the mandibular contour while gently pushing inferiorly on the cheek. This simulates the effect of gravity on the upright face and may reveal the need for additional fat excision from this area.

Once skin and SMAS flaps have been elevated, but before the SMAS has been sutured and preplatysmal lipectomy is complete, the surgeon should examine the neck intraoperatively to decide whether the subplatysmal space needs be explored. Exploration may be indicated if a significant collection of *subplatysmal* fat was identified preoperatively or if large digastric muscles or submandibular glands are present. Significant accumulations of subplatysmal fat can be demonstrated intraoperatively by placing gentle superior traction on the cheek flaps and flexing the neck. If the neck appears full with this maneuver, the surgeon should consider exploring the subplatysmal space and removing redundant subplatysmal fat.

The subplatysmal region is explored through the submental skin incision, and the subplatysmal space is entered by incising the superficially situated fascia between the medial platysma muscle borders. A combination of blunt and sharp scissors tech-

nique is used to isolate each muscle edge. The muscle edge is then grasped and the dissection carried laterally over the anterior belly of the anterior belly of the digastric muscle hugging the underside of the platysma. If this dissection is carefully done, a well-defined, relatively avascular plane can usually be identified. Small communicating vessels are not infrequently encountered, especially near the medial muscle borders; these should be carefully fulgurated and divided.

Subplatysmal fat should be left on the deep surface of the neck and not raised with the platysma flap. This will facilitate fat removal, since it is technically difficult to resect fat from the undersurface of the muscle.

The plane tangent to the anterior bellies of the digastric muscles should be used as a landmark for the limit of subplatysmal fat removal. All fat lying superficial to this plane should theoretically be removed to achieve an optimal contour. As a practical matter, the overall neck contour must be considered, because it is the curvilinear plane across the submental region tangent to the borders of the mandible and the anterior bellies of the digastric muscles that ultimately determines an attractive neck contour. If large submandibular glands and/or anterior bellies of the digastric muscles are present but are not addressed, subplatysmal fat removal should be more conservative if accentuation of these problems is to be avoided. Fibrous fat in the prehyoid region should not be arbitrarily removed, especially in women, to prevent accentuation and masculinization of the larynx. If prominent submandibular glands and digastric muscles are appropriately treated, however, subplatysmal fat can be resected more aggressively, allowing optimal neck improvement.

Once the platysma muscles have been undermined, subplatysmal fat will be evident as a triangular fat pad with its base lying at the hyoid and the tip near the mentum. It should be removed incrementally, as appropriate, and as determined by the position and size of the digastric muscles and the size of the submandibular glands. Fat removal should not be arbitrary, and the surgeon must pay close attention to the new contours created. Subplatysmal fat excision often results in the division of tributaries of small pretracheal vessels, and a long, shielded cautery forceps and good suction should be available to obtain adequate hemostasis when required.

Fat situated deep to the plane tangent to the anterior bellies of the digastric muscles and beneath the deep cervical fascia (deep cervical or intradigastric fat) should rarely be removed, and *the overwhelming temptation to “clean out” the deep cervical space must be resisted. Platysmaplasty and other maneuvers cannot compensate for overzealous excision of deep fat, and in time, an objectionable submental depression will appear in the neck of a patient treated in this way.*

Submandibular Gland Reduction

If a large submandibular gland is present, it can usually be seen and palpated lateral to the ipsilateral belly of the anterior digastric muscle within its respective submandibular triangle, protruding inferiorly to a plane tangent to the digastric and the mandibular border. The protruding portion can be incrementally resected through the submental incision before the submental platysmaplasty is performed to improve neck contour, if indicated.

Prominent submandibular glands will be encountered as subplatysmal dissection is carried over the anterior belly of the digastric muscle. The prominent gland will appear as a smooth pink to tan mass covered by a smooth capsule. Reduction is begun by incising the capsule overlying the gland inferomedially just lateral to the anterior belly of the digastric muscle with Metzenbaum scissors. The submandibular gland will be evident once exposed in this manner because of its distinctive lobulated appearance. Its inferior portion can be grasped and easily separated from adjacent tissue inside its capsule with a gentle blunt scissors-spreading technique. Although all vital structures are outside the glandular capsule, care should be taken when mobilizing the gland superolaterally, because both the retromandibular vein and the marginal mandibular branch of the facial nerve are in close proximity in that area.

An examination of the gland, once separated from its capsule, will reveal it to be large, not merely ptotic; this observation forms the basis of the recommendation that partial resection be performed. In addition, examination of the exposed gland will clearly demonstrate that attempts to reposition it more superiorly will ultimately be fruitless.

The key to safe performing the procedure is adequate mobilization of the gland; modest overmobilization will make both gland resection and the control of any intraglandular bleeding much easier. Once adequately mobilized inside its capsule, the redundant, protruding portion of the submandibular gland is excised with an extended blade-tipped cautery and a long pair of insulated forceps. As in all surgery of the neck and the submental region, a fiberoptic headlight or retractor is essential, as is a competent assistant and a second scrubbed person to pass instruments and sutures as needed. One person cannot safely perform both these roles. A suction cannula or smoke-evacuating retractor should also be placed, and the position of the cautery tip relative to vital adjacent structures must be known at all times during the resection. If a smoke-evacuating retractor is used, a second Y-anchor suction setup should be available in the event that bleeding is encountered during the resection.

The inferior portion of the gland is firmly grasped and pulled gently inferiorly and medially out of its fossa, away from adjacent structures. The redundant portion is

subsequently incised incrementally under direct vision in a medial-to-lateral direction along the planned line of resection with coagulating current cautery. Gland excision should be performed so that the portion protruding inferior to the plane tangent to the ipsilateral anterior belly of the digastric muscle and the ipsilateral mandibular border will be resected. Usually the initial resection should be conservative, and the gland is incrementally reduced thereafter, as required. It should never be necessary and is not appropriate to remove an entire gland. This would most likely result in a depression or other contour abnormality and could precipitate dry-mouth symptoms.

Submandibular gland reduction must not be performed without good light, proper instruments, suction, adequate exposure, sufficient personnel, and proper caution, since intraglandular vessels may be encountered. These vessels are more commonly encountered when larger resections are necessary and are most easily managed by immediate, thorough fulguration before further dissection is done. Typically bleeding will occur from both the gland and the specimen side, and this is usually best controlled by quickly moving the cautery back and forth between each end of the cut vessel. If only the gland side is cauterized, bleeding will frequently continue from the specimen side, obscuring the surgical field. If bleeding is brisk, the cut edge of the gland should be compressed with forceps and the vessel isolated. It may then be grasped with a second instrument and cautery applied. In these situations, the surgeon should consider placing a hemostatic suture of 3-0 chromic gut at the cauterized site to prevent postoperative bleeding. In the unlikely event that bleeding cannot be controlled by these means, the submandibular fossa should be packed with a gauze sponge and digital pressure applied against the cut gland edge for several minutes. In most cases, when the sponge is carefully removed, the bleeding will have stopped; the bleeding point can be sought and any suspicious areas cauterized.

Once initial excision of the protruding portion of the gland is complete, the submental region is reconstructed, as indicated. It is not necessary or productive to attempt to oversew the cut edge of the gland or close the glandular capsule. These maneuvers are technically difficult and could precipitate intraglandular bleeding or result in injury to nearby neurovascular structures. It is also not necessary or productive to cauterize the cut edge of the gland in an attempt to shrink or seal it. This typically results in more postoperative pain and swelling and prolonged submental induration.

When submandibular gland reduction is performed, a drain should be placed in the subplatysmal space and left in place for several days after the procedure. It is safest to perform the platysmaplasty before the drain is placed and then to perforate the platysma and thread the drain into place. If the drain is placed before the platysmaplasty, the drain could be caught in one of the sutures, making its removal difficult.

Submandibular gland reduction, although important in the rejuvenation of many necks, will not in and of itself result in attractive neck contour. Other problems must be identified and addressed to achieve optimal results.

Submandibular reduction should be regarded as an advanced technique. It should be undertaken by surgeons well versed in cervical anatomy and experienced in more basic maneuvers used to rejuvenate the neck. It is highly recommended that any surgeon uncertain of the anatomy of the submental triangle or the exact relationships of important structures in this area review them carefully before undertaking this dissection.

Partial Digastric Myectomy

The surgeon will encounter a small subset of patients who have objectionably large anterior digastric muscle bellies. Usually these are most easily identified after subplatysmal lipectomy and submandibular gland reduction has been performed, but they may sometimes be evident preoperatively in patients seeking secondary surgery. In these situations additional improvement in neck contour may be obtained by performing superficial subtotal anterior *digastric myectomy*.

Superficial subtotal anterior digastric myectomy is performed under direct vision, through the submental incision after the subplatysmal space has been opened, the platysma muscle mobilized, and subplatysmal fat and protruding portions of the submandibular gland resected, if indicated. The redundant portion of muscle is visually gauged and then simply picked up with forceps and tangentially resected with Metzenbaum scissors. The neck is reexamined and the maneuver repeated until an improved contour is obtained. Usually this entails the excision of 10% to 25% of the total muscle mass. Occasionally 50% to 75% or more of each muscle will need to be removed. Tangential muscle myotomy will typically result in variable amounts of superficial oozing, which is easily controlled by grasping the bleeding areas and applying cautery.

Superficial digastric myectomy, although important in the rejuvenation of many necks, will not in and of itself result in attractive neck contour. Other problems must be identified and addressed if optimal results are to be obtained.

Superficial digastric myectomy, although important in achieving attractive contour in some necks, should be regarded as an advanced technique. It should be undertaken by surgeons well versed in cervical anatomy and experienced in more basic maneuvers used to rejuvenate the neck. It is highly recommended that any surgeon uncertain of the anatomy of the submental region or the exact relationships of important structures in this area review them carefully before undertaking this dissection.

Anterior Platysmaplasty

Anterior platysmaplasty (see p. 1555, *bottom*) is performed in most patients and provides an improved result in most necks, especially when the patient looks down and flexes her or his neck. The purpose of platysmaplasty is to consolidate the neck. It cannot create contour in and of itself, and it is not adequate treatment for platysma bands in most patients. Typically platysmaplasty consists of suturing the medial muscle borders together from the mentum to the thyroid cartilage in one or two layers in conjunction with varying degrees of platysma transection (platysma myotomy) low in the neck. If redundant muscle is present medially, it is excised and discarded so that a smooth edge-to-edge approximation of the medial muscle borders can be made. Experience has shown that this produces a better result and reduces the likelihood that objectionable midline fullness or bands will result after the tissues have healed and relaxed than when excess muscle is invaginated and a multilayer “plication” is performed.

Platysmaplasty should be performed after checking the SMAS flap dissection and suspension to prevent general accentuation of the effects of aging and gravity and compromising rejuvenation of the face. Although this makes suture placement during the platysmaplasty more difficult, it allows optimal repositioning of the cheek and jawl. *If platysmaplasty is performed first, the cheek SMAS and lower facial fat will be pulled inferiorly and the improvements will be compromised.*

Platysmaplasty is usually performed using a combination of multiple simple interrupted and continuous sutures of 3-0 braided polyester sutures (or the surgeon's suture of choice) on a medium tapered needle beginning at the menton and working inferiorly to the cricoid. Long instruments are needed and patience is required. Optimal improvement generally cannot be obtained if the repair is done in one layer or if a running suture is initially used. If the first layer is performed using a running suture, some gathering and a purse-string effect can occur. This will result in shortening along the line of repair and can cause bow-stringing and the formation of midline bands. If the initial approximation is made with interrupted sutures, this problem is averted.

Next, the line of repair can be oversewn and reinforced with a simple running suture without a purse-string and shortening effect. The repair need only be snug, not tight. If a permanent suture is used, each should be immersed in antibiotic solution before placement, and care should be taken to bury all knots.

Platysmaplasty should be performed with the neck in a neutral position. If the closure is done with the neck extended, there may be excessive tightness when the patient looks down. This is particularly true if the platysmaplasty is performed in conjunction with a postauricular transposition flap of cheek SMAS.

If postauricular transposition flaps are planned, suspension to the mastoid should be performed after the anterior platysmaplasty is complete. If the transposition flaps are suspended first, the platysma muscles can be shifted laterally, and it may be difficult or impossible to adequately join them in the midline. Suspension to the mastoid is performed with interrupted sutures of 4-0 Mersilene (or another suture of choice). Usually the more proximal portions of the flap are secured with a simple running suture of 4-0 Vicryl. This consolidates the deep-layer repair in the perilobular area and prevents the flap from rolling on itself.

Transverse Platysma Myotomy

Although anterior platysmaplasty will often result in an attractive neck at rest and on the operating table, objectionable platysma bands and muscle striations will often still be evident in conversation and during animation if additional steps are not taken. These problems can be avoided by performing a *transverse platysma myotomy* (see pp. 1553-1555). The extent of platysma transection will depend on the deformities present and thus will vary from patient to patient.

Platysma myotomy should be performed after anterior platysmaplasty has been completed, when the platysma muscle is uniformly distributed over the anterior neck. Myotomy should be performed low in the neck at the level of the cricoid cartilage. At this level the muscle is thin and will bleed less, and the cut edges are less likely to be visible postoperatively. In addition, a smooth transition across the cervicomental angle is maintained. If transection is done higher, these benefits are lost and the larynx will be masculinized. This is particularly true when a myotomy is performed along the cervicomental angle or when wedges of platysma muscle are removed there.

An anterior platysma myotomy is best begun through the submental incision. The medial platysma border is identified over the cricoid cartilage and grasped and lifted away from the deep cervical fascia with a long DeBakey or similar type of forceps. Myotomy is then done by nibbling through the muscle in small increments with long Metzenbaum scissors. As the muscle is divided it usually separates a centimeter or more, exposing the fascia beneath it. Serrated and supersharp scissors should not be used, because they tend to pick up and cut adjacent tissue, and this can result in injury to the anterior jugular vein, which usually leads to copious bleeding that can be difficult to control. Gentle spreading with scissors tips before each cut helps separate the platysma from the underlying cervical fascia and facilitates dissection. The myotomy is continued laterally according to the preoperative plan. If a full-width division of the platysma is planned, the lateralmost portion of the transection is completed through postauricular incisions by identifying the lateral muscle border, incising it, and extending the incision to bring it into continuity with that made through the submental incision.

Final Contouring of Cervicofacial Fat

Once SMAS suspension, platysmaplasty, platysma myotomy, and other modifications of deep-layer tissues have been completed, final contouring of superficial cervicofacial fat can be performed. This should be done under direct vision using Metzenbaum scissors or a fine suction cannula. Final fat sculpting should be continued until all contours are smooth and regular, but *it is essential that not all fat be removed to produce an attractive, natural appearance*. Particular attention should be paid to the jawline and jowl areas. In addition, if the patient has a double chin or witch's chin, extended dissection of the perimental area and chin pad should be done, with fat contributing to these problems excised. Mental and submental fat should then be sculpted and blended to ensure a smooth transition from the mentum to the submental area.

Drain Placement

Drains are used routinely; experience has shown that they reduce postoperative ecchymosis and seromas and allow patients an earlier return to work and social activities. However, drains will not substitute for poor hemostasis and will not prevent hematoma formation. Drain placement should be performed before skin flap suspension and incision closure. A 10 Fr round, end-perforated Jackson-Pratt style closed-circuit suction drain is typically used in the neck. The drain is placed through a small stab incision on the occipital scalp 1 to 2 cm superior to the apex of the occipito-mastoid incision and anchored at its exit site with 4-0 nylon or a similar suture. The perforated portion of the drain is then passed beneath the cervical skin across the anterior neck to the opposite side of the face. When extensive modifications have been made to the anterior cervical and submental regions, or when diffuse oozing is encountered, one drain is placed on each side. This provides overlapping drainage of the anterior cervical area. Two drains are generally placed in most male patients as well. As mentioned earlier, if submandibular gland resection is performed, a separate drain is placed in the subplatysmal space.

Skin Flap Repositioning and Suspension Suture Placement

Skin flap repositioning and suspension suture placement should be performed with the patient's head in a neutral position, since flexion and extension of the neck will influence the amount of skin excised in the postauricular region. *To avoid an unnatural appearance, skin flaps must be shifted in a slightly more posterior, less superior direction than with the SMAS. It must also be remembered the goal of skin excision is to remove redundancy, not to tighten the skin flap.* Shifting skin along an overly superior vector or suspending skin flaps under tension will result in hairline displacement, poor scars, and other secondary deformities and objectionable problems.

Cheek skin flaps should be shifted along a vector roughly perpendicular to the nasolabial fold. When this is done sideburn elevation and displacement will be minimized, and skin will lie more naturally over the tragal region once healing is complete. An improved effect will also be obtained on the nasolabial area. In the neck area, skin should be shifted along a vector parallel to the mandibular border. This provides optimal improvement in the anterior neck and allows maximum excision of skin flap redundancy without compromising the skin flap's covering function. If the postauricular skin flap is shifted along a more superiorly directed vector, improvement in the anterior neck will be compromised, skin will be erroneously excised over the apex of the occipitomastoid incision, and a wide scar will be present once healing is complete.

There are two points of skin flap suspension that set the stage for the remainder of the closure. The first point is located in the supraauricular area, where the anterior-superiormost part of the ear joins the scalp. The cheek skin flap it is shifted along a vector roughly perpendicular to the nasolabial fold and skin redundancy is then gauged with a face-lift marker or similar implement. The skin flap should be held under just greater than normal skin tension for marking, and a small T-shaped incision is made into the flap at the marked point. Making the incision in a T shape facilitates suture placement and simplifies subsequent trimming of the flap. The flap is then anchored at this point with a half-buried vertical mattress suture of 4-0 nylon with the knot tied on the scalp side. No deep sutures are necessary.

The face-lift marker. The use of a flap marker provides a reliable means for appropriate excision of skin. The pin on the lower jaw of the marker is designed to be placed near the edge of the incision. The skin flap is then pulled over the lower jaw of the instrument, and when proper tension is set, the instrument is closed. Then the upper jaw of the instrument marks the precise position of the edge of the scalp flap beneath it. This serves as a valuable guide to the degree of redundancy present and is particularly useful in gauging the depth of "pilot" incisions initially made into the flap at points of initial flap suspension. The marker is shown in use. *Inset*, Close-up view of the tip design.

The second point of suspension is located in the postauricular area at the anterior-superior aspect of the occipitomastoid incision. The postauricular flap is shifted posteriorly and somewhat superiorly, roughly parallel to transverse neck creases and the mandibular border so that skin is suspended under minimal or no tension and that *little or no skin need be trimmed from the anterior (postauricular) flap border*. Excessive trimming of skin from the anterior border of the postauricular skin flap will require the flap to be shifted along an incorrect vector, and will compromise the result. The flap is then secured with a simple interrupted 4-0 nylon suture. No incision into the flap is necessary, and no deep suture is used.

Once the two key suspension sutures have been placed, the flap overlying the inferior portion of the ear should be carefully divided and the lobule exteriorized. *This is a key step in the procedure that must be performed incrementally and with great care to avoid a visible scar, lobular malposition, and objectionable secondary deformities*. If the incision to exteriorize the lobule is properly made, the apex of the incision should rest snugly against the inferiormost portion of the conchal cartilage. If the incision into the cheek flap is made too far anteriorly or inferiorly, however, artistically appropriate resetting of the lobule will not be possible, and the outcome of the overall procedure will be significantly compromised.

Skin Flap Trimming and Closure

Trimming of the skin flap and incision closure are conveniently begun in the postauricular area after initial suspension sutures have been placed and the lobule exteriorized. Postauricular closure along the auriculomastoid sulcus should be completed before trimming and closure of the occipital portion of the incision and resetting of the lobule. It is begun by conservatively trimming the anterior border of the postauricular skin flap into a soft curve to match the curve of the incision in the auriculomastoid sulcus. The incision is then closed with several interrupted 4-0 nylon sutures. No deep suture is used, and a watertight closure is not needed.

A small amount of skin only should be trimmed from the anterior margin of the postauricular flap along the auriculomastoid sulcus. If it appears that a large amount of skin needs to be excised from this area, the postauricular flap has been shifted incorrectly, both too far anteriorly and superiorly. If this occurs, the previously placed suspension sutures should be removed and the flap readvanced along a more appropriate and more posteriorly directed vector.

It is also an error to excise any skin over (superior to) the apex of the occipitomastoid incision and to shorten the postauricular flap along the long axis of the sternocleidomastoid muscle, as is commonly done. Despite an apparent redundancy in this area when the patient is supine on the operating table, there is never any true skin excess at this location. This pseudoexcess of skin is present only because of the patient's high shoulder position in the supine position; it will vanish when she or he sits up and the shoulders drop to a normal position. Skin along the axis of the sternocleidomastoid muscle is also needed for side-to-side head tilt. Inappropriate excision of skin over the apex of the occipitomastoid defect is the ultimate underlying cause of hypertrophic healing in the postauricular region and a wide postauricular scar (see p. 1596, *top*).

Trimming and closure of the occipital portion of the incision should be performed after closure of the postauricular area. If the occipital incision was made into the occipital scalp (see p. 1543), it should be closed without the excision of skin or scalp in one layer with multiple simple interrupted 4-0 nylon sutures. This incision plan is used to provide access to the lateral neck only and cannot by design accommodate skin excision in this area without producing displacement and notching of the occipital hairline. Because this incision is usually beveled when properly done, staples will not usually provide precise wound edge approximation. Sutures are generally required to avoid malalignment and step-offs.

If the occipital incision has been made along the occipital hairline (see p. 1545), skin only will be excised along the posterior border of the postauricular skin flap. A face-lift marker should be used to gauge skin flap redundancy, and all points along the flap should be intentionally trimmed with two to three millimeters of redundancy. It must be remembered that the goal of skin excision is to remove redundancy, not to tighten the cervical skin flap. *If trimming is performed correctly, the wound edges should abut one another and no gaps should be present before sutures are placed.* The incision is then closed in one layer with multiple half-buried vertical mattress sutures of 4-0 nylon with the knots tied on the scalp side and simple interrupted sutures of 6-0 nylon (see p. 1596, *bottom*).

No deep sutures are required, and staples should not be used. This will provide precise wound edge alignment and prevent crosshatched scars (suture marks). In addition, if the incision is closed under no tension, as described, the scar will be an inconspicuous scar.

If the postauricular skin flap has been shifted along a proper vector and tissue distributed appropriately under no tension over the occipital area, a precise fit should be obtained. If neck skin redundancy is large, or if the postauricular flap has been suspended under tension, a dog-ear will often be present at the inferiormost portion of the occipital incision. This should not be chased down the occipital hairline, because an obvious scar will result in the fine hair at the nape of the neck. A better result is obtained if the dog-ear is inset *posteriorly* into the occipital scalp, above the junction of thick and fine hair, and secured with simple interrupted sutures of 4-0 nylon. This requires that a small ellipse of scalp be excised from the *scalp side of the incision* but moves the end of the incision into dense hair where it is well concealed.

Skin flap redundancy should be carefully gauged using a face-lift marker while the pretragal portion of the skin flap is held down into the pretragal hollow with an instrument by the assistant. This ensures that enough skin will be present to fill the pretragal sulcus and to provide natural and attractive preauricular contours once healing is complete. This is also a key step in avoiding a “retracted tragus” deformity.

Preauricular closure is performed next. Using marks made by the face-lift marker as points of reference, the prehelical portion of the cheek skin flap is trimmed to form a soft curve that matches the prehelical incision. *If trimming is performed correctly, wound edges that abut one another and no gaps should be present before sutures are placed.* The incision is then closed in one layer with multiple simple interrupted sutures of 6-0 nylon or a simple running suture of 6-0 Prolene. No deep sutures are necessary.

The prelobular (subtragal) portion of the cheek skin flap is trimmed next, guided by marks made previously with the face-lift marker. If trimming is performed correctly, wound edges will abut one another, and no gaps should be present before sutures are placed. The incision is then closed in one layer with several simple interrupted sutures of 6-0 nylon. No deep sutures are necessary.

Once the prehelical and prelobular areas have been closed, the tragal flap is trimmed. This must be performed with great care while the assistant holds the pretragal portion of the skin flap into the pretragal hollow. As elsewhere in the periauricular closure, the tragal flap should be trimmed with 2 to 3 mm of redundancy. Closure is then made with simple interrupted 6-0 nylon sutures or a simple running suture of 6-0 Prolene. The tragal flap usually does not need to be thinned or defatted except along its posterior margin, and no deep sutures are necessary. Trimming the tragal skin flap too short is a serious artistic error that will result in tragal retraction and an unnatural chopped-off tragal appearance.

Incorrect trimming of the postauricular skin flap. It is an error to excise any skin over (superior to) the apex of the occipitotomastoid incision and shorten the postauricular flap along the long axis of the sternocleidomastoid muscle. There is no true excess of skin along this vector, nor any aesthetic benefit from shifting skin in this direction. Excision of skin in this fashion is the underlying cause of hypertrophic healing in the postauricular area and of a wide postauricular scar.

Suturing incisions along hairlines. *Left,* Wound edges are approximated with interrupted half-buried vertical mattress sutures of 4-0 nylon with the knots tied on the scalp side. *Right,* Final approximation with simple interrupted 6-0 nylon sutures.

Insetting the Lobule

There is nothing as telltale and aesthetically objectionable as an abnormal position of the earlobe. For this reason, *the lobule should be inset into the cheek flap as the last step in the closure of the periauricular area*. Trimming the cheek flap to inset the lobule must be performed with great care and should always be performed incrementally in stages to prevent overexcision. The cheek flap should be trimmed and the earlobe inset in such a manner that the lobule ends up situated in a natural and aesthetic appearing posterior and somewhat superior position, even if it was in a more anterior or inferior position before surgery. This is because the long axis of the earlobe of an artistically ideal, nonsurgical-appearing ear sits approximately 15 degrees posterior to the long axis of the ear itself in the lateral view. As this angle is reduced or shifted anteriorly, or if the lobule is mistakenly placed too far inferiorly, an elderly, unnatural, face-lift look is produced.

Proper insetting of the earlobe. In an artistically ideal, nonsurgical-appearing ear (*left*), the long axis of the earlobe (*dashed line*) sits approximately 15 degrees posterior to the long axis of the ear itself (*solid line*) in the lateral view. As this angle is reduced, or the axis of the lobule shifted anterior to the long axis of the ear, an elderly, unnatural, face-lift look is produced (*right*).

Insetting the lobule into the cheek so that its long axis sits posterior to the long axis of the rest of the ear often requires that the lobule be released from tethering tissue. It is then secured in two layers. The first layer consists of several deep dermal sutures of 4-0 Monocryl. These sutures provide initial alignment and protect the incision from disruption in the first few weeks after surgery when the patient pulls clothing, jewelry, and other items off over the head. Final approximation is then made with a simple running suture of 6-0 Prolene. A running polypropylene suture is usually eas-

ier to remove than a running or interrupted suture of 6-0 nylon, although either method of suturing will suffice.

If the lobule has been inset correctly, there will often be redundant skin on the posterior surface of the ear at the lobular-conchal junction. This is easily and conveniently managed by excising a triangle of skin corresponding to the tissue redundancy in this area. Closure is done in one layer with several simple interrupted sutures of 4-0 nylon or another suture of choice.

If foreheadplasty is to be performed as part of the procedure, closure of the temporal portion of the face-lift incision is delayed until after it is complete. This preserves access to the upper lateral face and affords precise realignment of tissue in this area.

If the temporal portion of the face-lift incision has been made on temporal scalp (see p. 1537), the incision is closed in one layer *without excision of any hair-bearing temporal tissue* with multiple simple interrupted sutures of 4-0 nylon. A small amount of cheek skin and scalp only will be excised immediately above the ear at the completion of the closure. Because a properly made incision on the temporal scalp is usually beveled, sutures, not staples, are generally required to avoid malalignment and step-offs. *It is clinically unproductive, a conceptual error, and a serious technical mistake to excise scalp over the temple region in attempt to improve the forehead or upper lateral face.*

If the temporal portion of the face-lift incision has been made along the temporal hairline (see p. 1538), skin only will be trimmed when it is closed. A face-lift marker should be used to gauge temporal skin excess and the flap intentionally trimmed with 2 to 3 mm of redundancy. *If trimming is performed correctly, wound edges should abut one another and no gaps should be present before sutures are placed.* The incision is then closed in one layer with a combination of half-buried vertical mattress sutures of 4-0 nylon, with the knots on the scalp side, and simple interrupted 6-0 nylon sutures (see p. 1596). Staples should not be used. This scheme will provide precise wound edge alignment and will prevent crosshatched scars (suture marks).

Once all other incisions have been sutured and all concomitantly performed procedures have been completed, the submental incision is closed. Closure of the submental incision is usually delayed in this manner so that a final check for hemostasis can be made. If closure is done earlier in the sequence of the procedure, subsequent oozing in the neck can require that the incision be reopened to control it. The incision is closed in two layers to ensure precise approximation of subcutaneous fat and skin. If a more casual closure is done, irregularities may result that will draw attention to the scar. The first layer of closure is accomplished using several deep dermal sutures of 4-0 Monocryl. Final approximation is made with a simple running suture of 6-0 Prolene.

Instrument Tray for a Face Lift

	Number	Instrumentation
Scalpels	2	Scalpel handle (round) (Padgett P-650)
Skin Hooks	2	Double-pronged skin hook (10 mm) (P-5379)
Needle Holders	4	Needle holder long (7") (narrow carbide jaw, gold handled) (V. Mueller CH2492)
	4	Needle holder medium (carbide jaw, gold handled) (Padgett P-2410)
	3	Needle holder large (carbide jaw, gold handled) (Jarit 121-135)
	4	Needle holder, Webster (smooth jaws) (Storz N5712)
Scissors	1	Tenotomy scissors (V. Mueller OP 5675) (forehead)
	1	Kaye scissors (carbide jaw-gold handled) (P29065)
	1	Metzenbaum scissors (med) (Padgett P-6468)
	1	Suture scissors (small "baby Metz")
	1	Utility scissors (large straight Mayo) (Pilling LL3)
Forceps	1	Adson (carbide with fine w teeth) (P 2511)
	1	Adson (carbide with medium w teeth)
	1	DeBakey (8" fine-toothed jaws) (Codman 37-1011)
	1	Coagulating forceps (black insulation) (SP 0531)
	5	Allis forceps (Storz N-5600)
	12	Mosquito hemostat (Storz)
	2	Curved Kelly hemostat (for peanut sponges)
	4	Straight Kelly hemostat
	2	Snitz forceps (long)
	1	Right-angle forceps (long)
Retractors	1	Malleable (small) (Padgett 4206)
	1	Malleable (large) (Padgett P-4341)
	1	Army (Codman 50-4071)
	1	Freeman (Padgett P-491)
	1	Freeman rake (four pronged) (Padgett P-509)
	1	"Wound protector" (modified Des Marres retractor)
	1	Ragnell retractor (double ended)
Miscellaneous	4	Towel clip (small)
	4	Towel clip (large)
	1	Obwegeser periosteal elevator (Padgett 7710)
	1	Metal ruler
	1	Metal comb
	1	Marten flap marker
	1	Yankauer suction (metal) (N7550)
	1	Frazer suction and stylet (2 pieces)
	2	Hair clip
	1	Ring/sponge forceps
	2	Zimmer blue plastic clip
	1	Headlight joystick
	1	Instrument retainer
	1	Needle tip cautery
	1	Cautery, long tip
	1	Cautery, short tip

Completion of Concurrently Planned Procedures

When the face, neck, and forehead lifts are completed, attention is turned to upper blepharoplasty, lower blepharoplasty, perioral dermabrasion, and other planned procedures, as indicated.

Dressings

After all planned procedures have been completed and all incisions closed, the patient's hair is shampooed and rinsed with warm tap water that has been allowed to stand for a few minutes with a few drops of povidone-iodine added. The sutured incisions are given a final inspection. If poor alignment is found in any area, it is locally reprepared and sutures are removed and replaced, as required.

Once the patient's hair has been shampooed and rinsed, conditioner is applied and the hair is carefully detangled with a wide-toothed comb. Failure to adequately wash, condition, and detangle the patient's hair after completion of the procedure can result in matting and tangling that can be problematic in the postoperative period.

No dressings are required or applied. Dressings traditionally applied over the face and neck after face-lift surgery create a tourniquet effect and accentuate swelling in the face, regardless of how carefully they are applied. These dressings were needed for two reasons. First, traditional face-lifts were usually closed over large Penrose-type drains that were typically left protruding from a loosely closed postauricular incision. A large, bulky, helmet type of dressing of mineral oil-soaked cotton secured with a shell of rolled gauze was required to catch blood and serous fluid and prevent it from soiling the patient's clothing, belongings, and carpets. Second, a pressure dressing was needed to hold undermined facial flaps against the underlying face and to close down subcutaneous dead space. The use of closed suction drains has simplified the management of these problems and eliminated the need for a dressing.

Every surgeon seeking the best result and the fewest complications should give careful consideration to the need for a traditional face-lift dressing and its possible drawbacks. Although those who use a face-lift dressing claim it prevents seromas and hematomas and provides increased patient comfort, experience, simple logic, and common sense all indicate otherwise. There are many compelling arguments against the use of a face-lift dressing—perhaps the most compelling of which is the very real danger of compromising circulation in delicate, widely undermined cervicofacial skin flaps. Dressings also limit the ability to directly observe the face and neck and may conceal an evolving or established problem. In addition, little about a face-lift dressing is comfortable. Most are tight and confining; they obstruct hearing, complicate facial hygiene, and needlessly attract unwanted attention. In my experience, patients, when given the choice, almost always prefer to do without them. If the sur-

geon chooses to use a dressing, there should be a good reason for doing so, and it should be confirmed that it does the patient no harm.

Patients are typically discharged with a hat, scarf, and sunglasses. If dermabrasion or lip augmentation has been performed, a rigid disposable surgical mask that rests off of the perioral area is also usually applied.

Postoperative Care

Performing the procedure itself fulfills only part of our obligation to the patient, and the care they receive postoperatively is arguably as important as the surgery itself. Diligent postoperative care will also ensure the best result and limit the likelihood that problems and complications will occur.

All patients are discharged to an aftercare specialist with specific written instructions as to how they are to care for the patient. I am always available to answer questions and see any patient, if needed. Patients are asked to rest quietly and apply iced compresses to their eyes for 15 to 20 minutes of every hour they are awake for the first 3 days after surgery, even if they have not had eyelid surgery as part of the procedure. For most patients, edema peaks at about this time. It is not necessary or productive to apply ice compresses continually throughout the day or at night. It has not proved necessary, and it is generally not well tolerated by the patient, to apply iced compresses to the cheeks, neck, or forehead. If the patient has had lip augmentation, ice compresses are applied to the perioral area in a similar manner and on a similar schedule. Recently we have found that a commercially available water-cooled face mask simplifies and improves the experience for many patients. Unlike traditional wet compresses, these masks apply continuous dry cooling that is well tolerated even when sleeping.

All patients are provided oral analgesics, sleep medications, antiemetic suppositories, bland ophthalmic ointment, and preservative-free artificial tears solution with specific instructions for their use. Patients are required to use ophthalmic ointment each night for the first 3 weeks after surgery or until all signs of eye irritation have abated. Artificial tears are used throughout the day, as needed. Patients are also informed that eyedrops are not sufficient for night use.

All patients are instructed to sleep flat on their backs without a pillow. A small cylindrical neck roll is permitted if the patient requests it and/or requires it. This posture ensures an open cervicomentral angle and averts dangerous folding of the neck skin flap and obstruction of regional lymphatic vessels that inevitably occurs if the patient is allowed to elevate the head on pillows, as is commonly recommended. In ad-

dition, swelling will drain to the back of the head instead of the neck in this position, where it is not harmful and is less noticeable and more rapidly transmitted away from the head and neck area when the patient sits upright.

All patients are shown an elbows-on-knees position that ensures an open cervicomental angle while sitting. This posture places the patient's book, magazine, paperwork, notebook computer, or meal in a position that allows reading, writing, eating, and TV watching in comfort and safety, with the patient's chin up and the neck extended. Other sitting postures typically result in unavoidable neck flexion and related problems.

All patients should be examined the morning after surgery, if possible. This visit, although sometimes inconvenient, is important to identify incipient problems in an early, treatable stage. All sutures should be checked and any appearing too tight should be cut but left in place. Releasing potentially overtight sutures prevents necrosis and alopecia. Leaving the cut suture in place, rather than removing it, averts the annoying bleeding from the suture site that inevitably occurs if the suture is completely removed at that time. All flaps should be carefully inspected. *Whenever incipient compromise is noted, one must be suspicious that a tight closure has resulted in excessive tension over that area.* If compromise is suspected, the offending sutures should be removed, even if wound separation may result. Secondary healing of the incision is always superior and easier to revise than is a large area of more anteriorly situated full-thickness skin slough.

Patients are allowed to take a soft diet as tolerated after surgery but are encouraged to avoid salty, sour, dry, and difficult to chew foods. Patients are asked to abstain from drinking alcoholic beverages for 2 weeks after surgery and until they are no longer taking pain pills (acetaminophen included) or sleep medications.

Patients begin a daily routine of showering and shampooing no later than 3 days after their procedures. This helps remove crusting about the suture lines, keeps incisions clean and bacteria counts down, and usually improves the patient's general overall sense of well-being. It also facilitates suture removal. Patients are instructed that they need not be as thorough as usual when washing their hair after their procedure and that they need not attempt to remove all dried blood and crusts. They are also assured that shower water, shampoo, and conditioners are not harmful and will not cause infection. Showering and shampooing are permitted even when drains are still in place.

Forehead drains are generally removed the morning after surgery by the aftercare nurse or when the physician checks the patient. At least one drain is usually left in the neck until the first suture removal visit however. This is because drain output often quickly falls on the second or third day during the time the patient is mostly supine and resting but then picks up again when the patient begins to spend more

time upright and starts to move her or his head about more. Leaving the neck drain in for 4 to 5 days will reduce the likelihood that small collections will form and will speed the overall resolution of edema and ecchymosis in the neck area.

Sutures are removed in two visits over 7 days. Fine sutures are removed on the first visit 4 to 5 days after surgery. Half-buried vertical mattress sutures and scalp sutures are removed on the second visit 7 days after surgery. It is usually not productive to try to remove sutures hidden under dried blood or crusts along suture lines; these are usually removed at a third visit approximately 2 weeks after surgery, at which time crusts are gone and sutures are readily identified.

Patients should be warned that their scalp and parts of their face may be partially numb after surgery and that they must be careful when bathing that shower water is not too hot and that hairdryers are not used on high heat settings. Patients are also instructed not to get a permanent or tint, dye, highlight, color, or otherwise chemically treat their hair for 2 weeks after surgery, because these treatments can result in hair breakage or hair loss. Hot rollers and curling irons must be used with care for several months, because the patient can unknowingly burn her forehead and scalp.

Determining when patients can return to work and their social lives depends on their tolerance for surgery, their capacity for healing, the type of work they do, the activities they enjoy, and how they feel overall about their appearance. Patients are asked to set aside 2 to 3 weeks to recover from surgery. Additional time off is recommended before an important business presentation, family gathering, vacation, or other important event. If the patient is doing well and not experiencing problems, she or he is allowed to return to light office work and casual social activity 9 to 10 days after surgery. It is often wise to begin with a limited workday at first and to adjust their schedules thereafter. If a patient's job entails more strenuous activity or physical labor, a longer period of convalescence may be required. Patients are advised not to drive for the first 10 days after surgery until they are feeling well, their vision is clear, and they have stopped taking pain medications.

Patients are advised to avoid all strenuous activity during the first few weeks after surgery, including heavy lifting, stooping, straining, and bending forward, and are informed that aerobic activities and exercise can result in internal bleeding and hematoma formation. Two weeks after surgery, patients are allowed to begin light exercise and gradually work up to their presurgical level of activity; 4 to 6 weeks after surgery, they are allowed to engage in more vigorous activities, including most sports, as tolerated.

Patients are informed that it may take 2 to 3 months for them to look good in a photograph or to be seen at an important function. They are also advised to expect some numbness and firmness in the face and submental areas for 6 to 9 months or more.

Results

Face Lift: Obtaining a Soft, Natural Appearance

Whenever prospective patients and the lay public discuss face-lift surgery, they will inevitably express the most concern and dismay over the tight faces of various celebrities and their friends and acquaintances that have undergone the procedure. Many will unhesitatingly demonstrate what they see to be the problem by pulling forcefully on their cheeks, eyes, and eyebrows, asking either not to look that way after their surgery, or stating they will never undergo surgery for fear of ending up with a similar appearance. This is reinforced by the numerous jokes and references in the popular press to “masks,” “wind tunnels,” and “faces so tight they will crack” if the individual smiles. Despite these expressed concerns and the frequent popular ridicule of the typical outcome of skin-only face lifts, procedures based predominantly on skin tightening continue to be performed.

The fundamental problem with the traditional skin-only face lift performed by many surgeons is that skin is meant to serve as a covering function, not a structural, supporting one. Most of the changes seen in the aging face are the result of an attenuation of support and subsequent descent of deep layer facial tissues however, and not sagging of skin. Any attempt to lift significant sagging of deep facial tissue with skin will be short lived and destined to produce an overly tight appearance and other telltale and objectionable problems.

The following patient example shows that when modern two-layer SMAS face-lift techniques are used and tension is diverted to deeper layers of the face, a soft, natural appearance with few telltale signs that surgery has been performed can be obtained.

This 42-year-old woman had a suboptimal eyebrow position and configuration, cheek and jawline laxity, and hollowness in the cheeks and under-eye area. Even when smiling, she had a somewhat sad and melancholic appearance. She had had no prior plastic surgery. The same patient is shown 13 months after a face lift, neck lift, a limited-incision forehead lift, conservative upper and lower blepharoplasties, correction of ptosis, fat injections, and an upper lip lift. A small nevus on her neck was also removed. No skin resurfacing, facial implants, or other ancillary procedures were performed. She now has soft, natural facial contours, with no tight, pulled, or face-lifted appearance. Her improved eyebrow position gives her a more youthful, feminine, alert appearance. The cheeks and jawline have been lifted and redundant skin removed. Hollowness in the upper cheek and under-eye area has been filled by lifting sagging cheek tissue to a youthful position and by fat injections. She also had her teeth whitened and straightened after the surgery was performed.

After surgery, improved eyebrow position and restoration of cheek fullness are evident, as well as an improved transition from the lower lid to the cheek, elevation of the corners of the mouth, a smooth jawline, and improved neck contour. The lip lift has shortened the distance from the bottom of her nose to the upper lip border and improved the appearance of her mouth. The patient's face has a lighter, fresher, more alluring appearance.

In the preoperative lateral view, eyebrow ptosis, lower lid fullness, a tear trough, sagging cheek and jowl, a “drool line,” and neck laxity can be seen. The patient appeared tired and unfit, even though she was trim and in excellent overall health. Postoperatively, her results are as described above. No scars are visible, there is no distortion of the ear, and the earlobe is in normal position. In the down-tilted view, her neck laxity and poor neckline could be seen preoperatively, presenting an elderly, unfit appearance. Postoperatively, she now appears young, fit, and attractive.

Face Lift for Ethnic Patients

Hispanic patients, like Asian and black patients, often have elastic skin that stands up comparatively well to the sun and as a result, typically ages well. Because these patients often develop skin wrinkles comparatively late in life, they are thought by many surgeons performing traditional skin-only face lifts to benefit minimally from such procedures. In addition, people of ethnic ancestry with darker complexions are also thought to form poor scars and are typically deemed to be poor candidates for surgery on this basis.

A careful examination of the next patient's face before surgery shows that although minimal skin wrinkling and redundancy are present, there has been a loss of youthful facial contour. This loss of shape and contour results from sagging tissues under the skin; the improvement shown in the postoperative photo demonstrates the effectiveness of repositioning it by tightening the underlying SMAS layer. It is also evident that when tension is diverted away from the skin to deeper structural layers of the face, healing will be excellent and scarring minimal. This patient demonstrates the importance of addressing deep-layer aging, the effectiveness of the SMAS procedure, and that patients with good skin and minimal wrinkling can still benefit significantly from a properly performed procedure. In addition, if tension is diverted off the skin and transferred to deeper layers, healing of incisions will generally be excellent and inconspicuous scars will result.

This 55-year-old Hispanic woman had sagging cheeks, heavy jowls, lower eyelid fullness, deep nasolabial lines, and thin lips. The patient has a somewhat stern and disapproving appearance. She has had no prior plastic surgery. The same patient is shown 18 months after a face lift, neck lift, limited-incision forehead lift, upper and lower blepharoplasties, chin augmentation, and fat transfer to the lips and cheeks. No skin resurfacing or other ancillary procedures were performed. Postoperatively, smooth facial contours and a more youthful facial shape are evident, with an absence of a pulled or a face-lifted appearance. There is a smooth transition between the lower eyelid and cheek, and her lips and cheeks are fuller as a result of the fat injections.

In the preoperative scowling view, it can be seen that the patient had strong corrugator muscles that produced deep creases and an intense, angry appearance. The patient is seen after surgery trying to frown; she is no longer able to do so because of muscle modification performed as part of the forehead lift procedure.

In the oblique view her sagging cheeks and jowl and the hollow undereye areas are evident. Postoperatively cheek fullness has been restored, the transition from the lower eyelid to cheek is improved, the corners of her mouth have been elevated, and she has a smooth jawline and an improved neck contour. The lateral and down-tilted views show that her lower eye bag, tear trough, sagging cheek and jowl, thin lips, drool line, poor neckline, and weak chin have been restored to a more attractive and youthful appearance. The chin implant has produced a natural-looking profile that is in better balance with the rest of her face. No scars are visible, there is no distortion of the ear, and the earlobe is in normal position.

Face Lifts: Then and Now

Although skin tightening has been a traditional part of face-lift surgery since the inception of such procedures, the assumption that it is logical and productive has come under question in recent years. The reasons for this are numerous and are becoming increasingly hard for less-experienced surgeons, and patients themselves, to ignore.

Contrary to past assumptions, facial aging is in reality predominantly a process of loss of contour, rather than one of loosening and wrinkling of the skin. The skin, in large part, merely descends with the sagging tissue beneath it and sags to a lesser degree on its own. Skin is intended to serve a covering function, not a structural or supporting one. It is inherently elastic and evolved to accommodate tissue shifting and displacement associated with facial movement and expression. As such, skin cannot reasonably be expected to provide sustained support for sagging deeper facial tissues.

It is now recognized by many surgeons performing procedures to rejuvenate the face that skin tightening flattens facial contour rather than restoring it. Pulling on the skin flattens the contours that make the face appear youthful and distinctive, much in the way that stretching a rubber sheet or nylon stocking over it would. Skin tightness looks unnatural; not even infants and children have tight skin. Instead, they have an appropriate amount of skin to cover their youthfully contoured faces.

If skin is used as a vehicle for repositioning sagging deeper facial tissue, secondary deformities including poor scars and earlobe malposition will occur. In addition, using skin to reposition sagging tissue requires it to shift unnaturally in an upward direction. This can result in hairline and sideburn elevation, objectionable shifting of neck wrinkles onto the face, and other unnatural appearances.

When the face is lifted using the deeper SMAS layer instead of skin, skin can be re-draped under normal tension and in a more natural direction. When treated in such a manner, skin appears to be capable of undergoing some degree of self-repair and contraction, and this adds further to the improvement obtained. This concept forms the basis of the lamellar (two-layer) and bidirectional (two-directional) maneuvers used in modern face-lift techniques.

This 65-year-old woman had a high forehead, asymmetrical eyebrows, cheek and jawline laxity, neck bands, deflated lips, and hollowness in the undereye area. Despite a bright smile, she had a somewhat tired and melancholic appearance. She had previously undergone upper and lower blepharoplasties by another surgeon. She is shown 13 months after a face lift, neck lift, forehead lift, upper and lower blepharoplasties, perioral dermabrasion, and fat transfer to the cheeks and lips. No skin resurfacing, facial implants, or other ancillary procedures were performed. Note her soft, natural, facial contours and the absence of a tight, pulled, face-lifted appearance. Eyebrow asymmetry has been improved. The cheeks and jawline have been lifted and redundant skin removed.

The patient had a large submandibular salivary gland, seen as fullness in the upper neck area. Postoperatively the salivary gland has been reduced in size to obtain optimal neck contour. In the down-tilted view her neck laxity and poor neckline gave her an elderly, unfit appearance. After surgery, her well-defined jawline and create a more attractive, fit appearance.

The Concealed-Incision Face Lift

Considerable focus has recently been placed on shortening face-lift incisions as less-experienced surgeons have begun performing procedures to rejuvenate the face. More often than not, these short scars end up being wide, irregular, poorly positioned, or otherwise visible, and the procedure is of questionable benefit to the patient. The real goal in incision planning is to design incisions that provide the surgeon adequate access to the deep layers of the face that are simultaneously *well concealed* and do not result in hairline displacement. In properly performed face lifts, patients should be free to wear their hair any way they wish afterward, and they should not need to wear large earrings and heavy makeup to conceal the fact that they have had surgery. It is evident that many surgeons are still struggling with concealing face-lift scars when one notices that the area in front of the ear is typically hidden by hair or large earrings or is cropped out of the picture in postoperative photos of face-lift patients shown in informational brochures, books, magazine articles, and websites.

The irony of misguided attempts to conceal face-lift incisions by shortening them is that a well-trained surgeon employing proper technique can obtain inconspicuous scars using a long-incision plan. The issue is not how long the scar is—it is whether the scar can be seen and will be noticed by others, and this is the philosophy that underlies the concealed-incision face-lift technique.

A fundamental principle of the concealed-incision face lift is that inconspicuous healing cannot occur if there is skin tension; that tension must be diverted to deeper structural layers of the face, such as the SMAS and platysma. This cannot be achieved if the incision plan is too short, even if barbed suspension sutures are placed. It is equally important that incisions be placed along natural anatomic interfaces where the eye expects to see a natural line or a transition of skin color and texture. Scars placed in these locations appear to be part of the patient's natural anatomy or mimic naturally reflected highlights.

Finally, the eye will not be looking for scars if the outcome of the face lift is soft and natural appearing and there are no other telltale signs that surgery has been performed. In many cases a patient's friends and coworkers have refused to believe the patient has had a face lift, even if she or he admits it, if the patient's face is not tight and a concealed-incision plan is used.

The following patient is a case in point. It is evident that a marked improvement in the patient's appearance has been obtained, but there are no telltale signs indicating that surgery was performed. Her face has a soft, natural appearance, scars are concealed, and no hairline displacement or other irregularities are present.

This 48-year-old woman had a heavy jowl, overall facial laxity, and deflation in her cheek and undereye areas. She had had no previous plastic surgery. The same patient is shown 2 years and 11 months after a face lift, neck lift, limited-incision forehead lift, upper and lower blepharoplasties, fat transfer, and a shave excision of an unwanted nevus on her right upper lip. No skin resurfacing, facial implants, or other ancillary procedures were performed. Note the soft, natural facial contours and the absence of a tight, pulled, or face-lifted appearance. The cheeks and jawline have been lifted and redundant skin removed. Deflation in the upper cheek and undereye areas has been corrected with fat transfer. An existing scar on the left anterior neck has been released and fat grafted.

After surgery the patient's neck and jawline have been lifted and redundant skin removed. Note also that no distortion of the ear is present and the earlobe is in normal position. The patient appears fit, decisive, and more attractive.

Concluding Thoughts

The traditional “low” cheek SMAS flap elevated below the zygomatic arch suffers the drawback that it cannot by design have an impact on tissues of the midface and infraorbital areas. Low designs target the lower cheek and jowl only and produce little if any improvement in the upper anterior cheek region. Planning the flap “higher,” along the zygomatic arch, and extending the dissection medially to mobilize midface tissue overcomes this problem and results in a simultaneous lift of the face and midface together. A separate midface lift procedure is not required, and more comprehensive and natural-appearing improvement is obtained.

Clinical Caveats

It is not possible to design a universal face-lift technique. Each patient will have a unique set of problems that require precise anatomic diagnosis and an appropriately planned and individualized surgical repair.

Attractive, natural-appearing rejuvenation of the face is not possible without diverting tension away from the skin to the SMAS and platysma and unless other deep-layer structures and the aging midface are addressed.

Skin was meant to serve a covering function, not a structural or supporting one. Using skin as the vehicle to support sagging deep-layer tissue corrupts its function and results in abnormal tension and related secondary problems, including poor scars, tragal retraction, earlobe malposition, and a tight, unnatural appearance.

Using the SMAS to lift sagging facial tissues and restore facial contour circumvents the problems associated with skin-only face lifts, because it is an inelastic structural layer capable of providing meaningful and sustained support. Although skin must be excised in SMAS procedures, only redundant tissue is sacrificed, and closure can be done under normal skin tension.

Careful evaluation of most patients who need a midface lift will show that they also need a face lift. It is rare to encounter a patient with significant midface aging who does not also have sagging in the cheek and jowl, and a midface lift is arguably more logically performed in conjunction with a formal face lift than as an isolated, stand-alone procedure.

A drawback of the conventional low cheek SMAS flap elevated below the zygomatic arch is that it does not by design have an effect on tissues of the midface, perioral, and infraorbital regions. Planning the flap higher, along the superior border of the zygomatic arch, overcomes this problem and produces an improved result.

Continued

Clinical Caveats—cont'd

Lamellar dissections in which the skin and SMAS are dissected as two separate layers offer the advantage that skin and SMAS can be advanced different amounts, along separate vectors, and suspended under differential tension. This allows each layer to be addressed individually as indicated and in turn results in a more comprehensive and natural-appearing improvement.

Rarely does isolated aging occur in the lower face and neck, and nearly all patients requesting face-lift surgery are also candidates for forehead and eyelid surgery. Patients do not always recognize this fact, however, and must be carefully counseled in this regard.

Proper analysis, careful planning, and the use of an incision along the hairline, when indicated, can avert hairline notching and displacement without compromising the overall outcome of the procedure. This is particularly true of patients with marked skin redundancy and those undergoing secondary procedures.

Anterior platysmaplasty helps consolidate the neck but is *not* adequate or effective for the treatment of platysma bands. Effective treatment of platysma bands requires that a platysma myotomy be performed.

It is not enough in most situations to limit treatment of the neck to preplatysmal lipectomy and postauricular skin excision. For many patients, subplatysmal fat accumulation, submandibular salivary gland ptosis, and digastric muscle hypertrophy will contribute significantly to their neck deformity and necessitate additional treatment.

Although subcutaneous undermining is usually necessary in most necks, it should not arbitrarily include the entire face. If a SMAS dissection is planned, preservation of the anterior platysma-cutaneous ligaments will allow attractive and youthful appearing elevation of perioral tissue that cannot be obtained with a skin-only technique, or when wide skin undermining is performed.

SMAS flaps should be advanced along a posterior-superior vector parallel to the long axis of the zygomaticus major muscle. If a vertical or posterior vector is used, the function of the zygomaticus major muscle will be corrupted and abnormal appearances during animation may result.

Inappropriate excision of skin over the apex of the occipitomastoid defect is the underlying cause of hypertrophic healing in the postauricular region and ultimately of a wide postauricular scar. Although an apparent excess of skin will be present in this area when the patient is supine on the operating table, this skin is necessary once the patient's shoulders drop in the upright position, and for side-to-side head tilt.

Rejuvenation of the face is a considerable undertaking, and its difficulty should not be underestimated. The procedure must be carefully planned, meticulously carried out, and the patient's safety and well-being unfailingly ensured.

Performing the procedure itself fulfills only part of our obligation to the patient, and the care they receive perioperatively is arguably as important as the surgery itself. Diligent perioperative care will ensure the best result and reduce the likelihood that problems and complications will occur.

CHAPTER 47

Combined Face Lift and Facial Fat Grafting

TIMOTHY J. MARTEN

Recognizing the components of the aging deformity of the face and appreciating the underlying anatomic abnormalities are essential to selecting the appropriate treatment and planning surgical procedures. Careful analysis will reveal that most patient problems fall into three broad categories:

1. Aging and breakdown of the skin surface
2. Facial sagging, skin redundancy, and loss of youthful facial contour
3. Hollowing, wasting, atrophy, and/or age-related lipodystrophy of the face

Selecting the appropriate treatment will depend on the types of problems present, the patient's priorities, and the time, trouble, and expense she or he is willing to expend to obtain the improvement desired.

Patients primarily concerned with *surface aging* of their faces may not require formal open surgery; they may be able to achieve the improvement they desire through salon care and dermatologic surface treatments of the skin. These treatments include skin peels, skin resurfacing, intense pulsed light (IPL), chemodenervation (*botulinum* injections), injection therapy (with tissue fillers such as Restylane, Juvéderm, and Radiesse), and various forms of cutaneous laser and other treatments designed to remove or reduce age spots, spider veins, wrinkles, and other age-related skin surface imperfections.

Patients primarily concerned with facial sagging, skin excess, and *loss of facial contour* will achieve marginal, if any, improvement if only surface treatments are employed. They will require formal surgical lifts in which sagging tissue is repositioned and redundant tissue excised if these problems are to be properly corrected and an attractive and natural-appearing improvement is to be obtained. The misapplication of surface treatments of the skin to a sagging face with excess tissue will produce little more than a smooth, saggy face with no improvement in contour. This sort of "smooth-saggy" look, typically seen in an older patient who has undergone laser resurfacing, is unnatural looking, because patients with a loss of facial contour generally have concomitant skin surface aging. It is arguably more attractive and natural appearing to have a well-contoured face with a few wrinkles and surface imperfections than a smooth but saggy one.

In patients with significant *facial atrophy*, age-related hollowing, and loss of facial fat, improvement from both surface treatments of facial skin and surgical lifts will generally be suboptimal. Smoothing the skin will not hide a drawn appearance caused by loss of facial volume, and it is difficult to create aesthetically pleasing, natural, and attractive contours by lifting and repositioning tissues that have abnormally thinned and involuted with age. Using fat injections to restore lost facial volume is a powerful technique that is now acknowledged by most plastic surgeons and other physicians who treat the aging face to be the most important advance in aesthetic surgery in several decades or more. Properly performed, the addition of fat to areas

of the face that have atrophied from age or disease can produce a significant and sustained improvement in appearance that is unobtainable by other means.

Why Perform a Face Lift and Fat Injections?

Why not perform just a face lift? The answer to these questions lies in the multifactorial origin of facial aging, and the fact that fat is predictably lost from the face, which develops hollows as a person ages, in addition to sagging, drooping, and other gravitational effects. An isolated face-lift procedure, even when aggressively and comprehensively performed, only addresses tissue ptosis and redundancy and often produces a lifted but telltale hollow and an underrejuvenated look, sometimes referred to as a “cougar” appearance. Fat injections, however, allow the loss of facial fat to be treated concurrent with the face lift, and these appearances to be avoided.

All things being otherwise equal, a concurrent face lift and fat injections will produce a better result than either technique performed alone, and when a face lift is performed in conjunction with fat injections, both loss of contour and facial atrophy can be corrected, and optimal improvement can be attained. This 75-year-old patient, seen preoperatively on the left, had tissue ptosis and redundancy, and significant facial atrophy. On the right, she is shown 1 year and 17 months after a high SMAS face lift, a neck lift, a closed forehead lift, upper and lower blepharoplasties, and panfacial fat injections. Combined lifting and filling of her face has produced a better outcome than either technique could have alone. The patient has had hyaluronic acid filler placed in her lips.

Volumetric Rejuvenation

Fat injections have other advantages for the face lift surgeon: they provide *volumetric rejuvenation*, a new means by which to improve facial appearance and a new dimension for plastic surgeons to work in. Unlike injectable fillers, fat is autologous and produces a sustained and long-lasting improvement. In addition, fat injections may actually induce an improvement in facial tissue *quality* through an as yet not clearly defined “stem cell effect,” and when performed with a face lift may constitute, for the first time, rejuvenation in the true sense of the word.

Nomenclature

The nomenclature for autologous fat transplantation can be confusing, since surgeons and others who inject fat into the face have used various terms to describe the procedure. In addition, in an effort to market the procedure, many proprietary marketing names and catch phrases have been created, and these can be especially confusing to patients. In essence, the commonly used terms *fat transfer*, *fat grafting*, *autologous fat grafting*, *autologous fat transplantation*, *fat injections*, *lipofilling*, and *lipoinjection* all refer to the same basic procedure. We typically use the terms *fat injections* or *fat transfer* in our discussions with patients, because these are straightforward descriptive terms that do not include medical jargon and are most easily understood and remembered.

Additional confusion has been created by the term *stem cell face lift*, a procedure in which fat is variously injected into the face with the purported but as yet unproven benefit of tissue rejuvenation mediated through a “stem cell effect.” In most cases fat only is injected, but in some cases limited traditional face lifts are performed concurrently. At present it is a stretch of the available scientific data to make such a claim, and it is medically more correct to refer to the two procedures simply as combined but separate and distinct surgeries.

Drawbacks of Fat Injections

Performing fat injections in conjunction with a face lift has certain disadvantages that must be acknowledged, including the learning curve associated with any new procedure, the increase in operating room time, increased postoperative edema, a longer period of recovery, and the uncertainty of graft take. Certain patient misconceptions must also be overcome, including misguided notions held by many that injected fat can migrate or fall, or that fat injections will make the face “look fat.”

Personal Evolution in Fat Grafting in the Face

I performed my first fat grafting procedures almost two decades ago; these were usually limited in scope, targeting specific areas such as the lips and nasolabial creases, as is the case for most beginning injectors. Over time, I began to address bigger problems that were otherwise difficult to treat, including overexcision of buccal fat by other surgeons, HIV-associated facial wasting, and the hollow upper orbit.

Buccal fat excision is often erroneously recommended as a way of creating a “high cheekbone” and a more angular facial appearance. In reality, it often produces an ill, haggard, gaunt appearance and an unfeminine look in women, especially when performed aggressively. This patient had buccal hollowing following buccal fat excision by an unknown surgeon. The patient is shown 11 months after fat injections to the buccal area. Fat was also placed in the infraorbital, midface, cheek, preoral, and jawline areas.

Still later, I expanded my use of fat injections to the treatment of thin-faced patients with significant atrophy but minimal sagging and redundancy who mistakenly believed a face lift alone would help them, and secondary and tertiary face-lift patients who had cervicofacial fat that had been erroneously removed by other surgeons during the primary procedures. For these secondary and tertiary face-lift patients, the fat injections quickly became more important than the face lift itself, and this remains true to this day.

This thin-faced man with marked facial atrophy but minimal tissue sagging and redundancy had had no prior surgery when he presented requesting a face lift. He is shown 16 months after fat injections to the infraorbital, midface, cheek, and jawline areas. No implants were placed, and a face lift was *not* performed. Improvement is evident in all areas, and the patient appears healthier, more fit, athletic, and masculine. A face lift alone could not have produced this kind of improvement and arguably might have accentuated his facial hollowness.

This woman had a previous face lift and related procedures performed by an unknown surgeon. She is shown 13 months after a combined secondary face lift and panfacial fat injections. She has also undergone foreheadplasty, eyelid surgery, ptosis correction, a neck lift, and perioral dermabrasion. Although the face lift allowed scars to be moved to more concealed locations and corrected her earlobe malposition, the replenishment of lost facial volume with fat injections was more important to the overall outcome of the procedure. Significant improvement of facial atrophy can be seen in the temples, upper and lower orbits, cheeks, midface, lips and perioral area, over the buccal recess, and along the jawline.

In time, however, I came to recognize that I was not obtaining full correction in many of my own primary face-lift patients, no matter how careful and technically proficient I was at lifting their ptotic tissue and removing excess skin. In most cases, regardless of how skillfully the procedures were performed, the patient still lacked the healthy, fit, and sensual appearance that younger faces with more facial fat had.

Other facts confirmed for me the concept that the volume addition to the aging face had artistic merit, including patients' and surgeons' preoccupation with the swollen face. I observed that patients overwhelmingly liked the appearance of their faces the first few weeks and months after traditional face-lift procedures, because the swelling present at that time gave them an almost surreally youthful appearance. Plastic surgeons also seem to like the swollen face for the very same reason, as is evident in the early face-lift results typically shown in advertisements, on the Internet, and even at scientific meetings and symposia. Although showing early results in these ways is deceptive and without scientific merit, it nevertheless affirms the importance of volume to an attractive and youthful appearance.

As groundbreaking as the idea of volume addition to the face was, at some point I came to realize that fat injections may offer something far more profound than just added volume, but I was slow to recognize this. My first realization that something above and beyond simple volume addition might result from fat injections was at an instructional course I was giving on face-lift surgery at a plastic surgery conference. After showing a large series of well-matched high-resolution before-and-after photographs of face-lift patients, a member of the audience raised his hand and inquired, "What type of laser and what energy settings are you using to resurface your patients?" I answered that other than limited perioral dermabrasion in some cases, none had had resurfacing of any kind. Confused by my response, he followed up by asking, "*Then why do they all look so smooth?*" Missing the significance of his question at that moment and the importance of his observation, my answer was simply that "they had had face lifts." I could not make any connection to the fat injections they had also received as part of their face-lift procedure. But he was seeing something in my patients that I had overlooked, or erroneously assumed to be solely the result of traditional surgery, that he was not seeing in his own face-lift patients. This difference is now known to very likely be the result of the much talked about but as yet not clearly scientifically defined "stem cell effect" obtained with fat injections. Simply put, fat contains "adult stem cells" that are thought to elaborate "growth factors" and other yet to be defined cellular "mediators" that appear to have a beneficial and regenerating effect on tissues adjacent to where the fat is injected, and it is likely that injecting fat into the face as part of a face-lift procedure has a rejuvenating and regenerative effect of this sort on the facial skin. Numerous anecdotal accounts and a growing number of scientific reports now support this idea, and fat

is currently being used to successfully treat atrophic scars, radiation necrosis, and other problem wounds that were previously deemed untreatable. It is my opinion, and that of other surgeons, that the combination of fat injections and dermabrasion is arguably the most effective treatment we currently have for perioral wrinkles, but this may be the result not only of restoring lost volume and the traditional improvement gained from dermabrasion, but also may reflect a direct regenerative stem cell effect. Only further research can conclusively answer the question as to whether fat injections can actually improve skin quality and facilitate healing through an adult adipocyte-mediated stem cell effect, but this is now a widely held belief by many clinicians.

Over time, I began to look beyond the lines and grooves on the face that had previously held my attention and that typically gain the notice of the traditionally trained eye, and I came to see the loss of facial fat as an undeniable and important *panfacial* occurrence requiring comprehensive replenishment. I have also since come to recognize the face as an incredibly nuanced sculptural form, and fat injections as an astonishingly powerful tool to improve the outcome of my face-lift procedures.

My initial attempts to discuss the importance of fat injections in rejuvenating the aging face with patients was met with confusion and skepticism by many of them. The initial reaction by most patients was that they were “already too fat,” and that fat injections would just make them “look fatter.” They could not see atrophy and loss of facial fat as part of the aging deformity of their face. As a result, my initial use of fat in my face-lift patients was to tell them that we would do their face lift first, move sagging tissues to a more youthful position, remove excess skin, then reevaluate them 6 months after the procedure and perform fat injections at that time, if indicated. In some instances patients would submit to a second-stage fat injection procedure, but for quite a while it was an uphill battle. Over time, however, the concept of adding volume to the face and the beneficial effects of doing so became known to prospective patients through the educational efforts of a handful of early adopters of the fat injection technique, through the resulting increased exposure of the procedure in the lay press, and through patients’ growing experience with nonautologous injected fillers. As patients came to understand the procedure and its benefits, they began to reject my suggestion that fat injections be performed as a second stage. Many patients began to arrive in my clinic knowing that fat injections were needed and did not feel they could take the time off from their personal and professional lives to undergo a second-stage procedure. These patients asked if I could do both their face lift and fat injections at the same time. I responded that I felt I could, and I was

stunned by the results when we did so. Today I feel as if I have “one hand tied behind my back” when I must perform a face lift without fat injections, and fat injections are now performed as part of most of my face-lift procedures.

Why Not Just Inject Fat?

Age-related loss of facial fat rarely exists as an isolated event in a healthy patient, and thus patients who are troubled by it are rarely logically or appropriately treated by fat injections alone. Isolated fat injections are also arguably of questionable benefit to a patient with significant facial sagging and skin redundancy. Although aggressive filling of the sagging face with fat can improve contours and produce a smoother skin surface, it generally results in an unusually large, overfilled, “filler face” that looks both unnatural and unfeminine. Such an overfilled face is hard to correct in an attractive manner at a later date, and it is both more logical and practical to perform fat injections in conjunction with formal surgical lifts if needed, or sometime *after* ptotic tissue has been repositioned and redundant tissue has been removed.

Where Should the Fat Be Injected?

Areas in need of treatment will vary among patients, and planning fat injections requires looking at the face in a different way—more as a sculptor—and less as a tailor as we have done in the past. Any area that can be successfully treated with nonautologous injectable fillers is potentially treatable with fat injections, including, but not limited to, the temples, brow, radix, upper orbit (upper eyelid), lower orbit (lower eyelid), cheeks, midface, lips and the perioral area, the nasolabial folds, genio-mandibular grooves, jawline, and chin—and experience with fillers is a useful point of reference for planning fat additions to the face. Perhaps the best way to decide where fat is needed is for the surgeon to study his or her face-lift outcomes carefully and identify areas where the procedure has fallen short. In most cases the biggest shortcoming for an experienced surgeon will be evident as a failure to replenish lost volume, and the areas in need of treatment will be obvious. In time, and after engaging thoughtfully in such study, one will gain a deeper appreciation of facial atrophy and an increasing desire to correct it.

This 45-year-old patient is shown before and 2 years and 4 months after a high SMAS face lift, neck lift, lower blepharoplasty, and fat injections. She had had no prior surgery. The shaded areas (*center*) show where fat was placed: 3 cc was placed in each upper orbit, 4 cc in each temple, 1 cc in each tear trough, 3 cc in each infraorbital area, 4 cc in each cheek, 2 cc in each nasolabial crease, 1 cc in each stomal angle, 2 cc in each geniomandibular groove, 3 cc in each lip, and 2 cc in the glabella, for a total of 50 cc of injected fat.

Sequencing Fat Injections With Other Procedures

When fat grafting is best performed during face-lift surgery has not yet been answered scientifically, but as a practical matter, it is most expedient to inject fat at the beginning of the procedure before the face lift itself has been started. The reasons for this include the fact that it is easier to harvest the fat at the beginning of the procedure, before the face has been prepared or draped, and when the patient is typically in a deeper plane of anesthesia. In the beginning of the procedure, the tissue planes of the face have also not been opened, the face is not swollen, and preoperatively made pen marks and facial landmarks are easier to identify. Finally, surgical principles suggest that it is also probably best to inject the fat before the start of the face-lift procedure to limit the time the harvested fat is out of the body.

Fat Injection Technique

The technique for facial fat grafting has been described in detail by Coleman, and we adhere to Coleman's principles when performing fat injections (see Chapter 13).

Logistics of Concurrent Face Lift and Fat Injections

Fat injections are viewed by many surgeons as a simple procedure that can be performed in a few minutes' time. However, this is rarely the case, and such an attitude will lead to frustration, disruption of the workflow, and poor outcomes. Fat must be harvested in a specific, atraumatic, and time-consuming manner if viable tissue is to be obtained that will survive and "take" at the facial recipient site. It must then be processed and injected in a technically demanding and time-consuming process that cannot be rushed. Fat grafting is also an *artistically* demanding activity that requires a considerable amount of the surgeon's intellectual, creative, and physical energy. When anything other than small amounts are being injected, the entire procedure can encompass an hour or more, something that can significantly tax an already overburdened surgical team engaged in a demanding operation entailing multiple procedures. Therefore time must be planned appropriately.

Equipment

Special blunt-tipped cannulas are required for injection, in addition to other specialized equipment for harvesting and processing the fat. Poor outcomes are typically obtained if sharp hypodermic needles are used to harvest or inject fat, or if fat is injected using a technique similar to that used to inject nonautologous facial fillers. Sharp-needle injection can also result in fat embolization and serious related problems and thus is not recommended.

Choosing a Donor Site

Currently there is no scientific unanimity as to where the “best” fat for grafting should be obtained. Donor sites are typically chosen and marked with the patient in a way that the fat harvest procedure will improve her or his silhouette, although the ideal locations are arguably the areas of diet- and exercise-resistant fat deposits where the fat is biologically programmed to be stubbornly persistent throughout the patient’s life. For women this is typically the hips, outer thighs, or abdomen, and for men the love handle and spare tire areas.

Although the lower abdomen might appear on casual consideration to be the easiest and best place from which to harvest fat, my experience has shown otherwise, and I prefer to take fat from the hip and lateral thigh when possible, if the patient agrees. There are several reasons for this. First, although using the abdomen as a donor site means that the patient does not need to be turned and that only one site is prepared and draped, abdominal fat is usually harder to extract, and the fat obtained seems to be more fragile and have a higher “oil” content. In addition, when anything more than a small amount is needed, the abdominal area is far less forgiving than the hip or the outer thigh because of the thinner, less elastic skin that is typically present, and postoperative irregularities and contour problems are far more likely to occur. For that reason, consideration should be given to placing the patient in a liposuction garment or abdominal binder if anything more than a small amount of fat is harvested from the abdomen. Harvesting fat from the hips and outer thighs requires that the patient be turned and that two areas be prepared and draped, but the fat in these areas is much easier to extract and the tissue obtained is usually more durable and nearly free of blood and oil. The hips and thighs also have thicker, more elastic skin, and I find that postoperative problems and contour irregularities almost never occur in these regions. Overall, patients are typically more pleased with the improvement in their figures when fat is harvested from their hips and outer thighs than when it is removed from their abdomen.

In thin patients, small harvests from multiple areas may be required, including the inner thighs, inner knees, upper buttocks, and anterior axilla, and this will add additional time to the procedure. It is recommended that the donor sites and site markings be photographed preoperatively to document what harvest sites were agreed on and to avoid any dispute over the patient’s preoperative condition after surgery.

Marking the Face

Fat injections cannot be placed arbitrarily; a careful plan must be marked preoperatively with the patient seated in an upright position. Marking will consume a significant amount time and is best carried out in a private area that is free from distractions. Creating an initial plan on a life-sized laser print of a photograph of the patient’s face is helpful in organizing one’s thoughts and facilitates the discussion with the patient as to which areas will be treated. In most cases marks are made in

conjunction with the patient while she or he holds a hand mirror so the plan can be discussed and clarified during this stage. The goal is to create a topographical map of the deficient and atrophic areas of the face to guide the surgeon during the procedure—essentially a reverse plan of that used when liposuction is performed.

Because an aging face is undergoing a process of *lipodystrophy*—that is, fat is becoming deficient in some areas and excessive in others—marks are also made where fat needs to be removed, when indicated. These areas can be marked in a different color or designated by some other means.

Once the markings are complete, additional photographs are taken of the patient's marked face and printed for use during the procedure. Some surgeons go so far as to have patients sign and date a laser print copy of the marked plan to avert any postoperative questions about what the patient's preoperative requests were and what was agreed on and consented to.

Anesthesia

Most modern face lifts are time consuming and technically demanding, and the addition of fat injections will test the patience and composure of most surgeons. It is highly recommended that the services of an anesthesiologist or experienced CRNA be enlisted when combined procedures are performed. This is particularly important when the procedure is to be performed on a patient who is apprehensive or has a history of anesthetic difficulties, hypertension, or other significant medical problems.

The majority of face lifts I now perform are done with the patient under deep sedation, administered by an anesthesiologist using a laryngeal mask airway. This allows the patient to be heavily sedated without compromise of the airway, but the patient need not receive muscle relaxants and can be allowed to breathe spontaneously. It is also easier to harvest fat from a heavily sedated patient, especially when fat must be harvested from multiple sites, and comprehensive treatment of the face with fat is facilitated under these conditions. However, any skillfully administered anesthetic is adequate for performing the procedure.

Harvesting Fat

Fat is harvested the day it is needed; it is not frozen or stored. There are several reasons for this. First, it would be a questionable practice to store harvested fat in casually labeled syringes in a small, unmonitored refrigerator/freezer of the type intended for home or office use. These devices typically do not provide around-the-clock monitoring of internal temperatures or have backup power, and most surgeons do not have the means to properly log in tissue to be stored and guarantee that cross-contamination, inadvertent thawing and refreezing, or mislabeling has not occurred. In addition, storage of fat in this manner could be construed as “tissue banking,” a practice that only licensed tissue banks are legally allowed to do in certain states.

More to the point, the preponderance of scientific information currently indicates that to be viable, fat must be flash-frozen to very low temperatures, much in the way that a human egg cell would; it will not be viable if slow-frozen in a typical food freezer and later thawed. Research and development in fat banking is underway, and in the future it is likely that surgeons will be able to store viable patient fat at a regional blood bank or a center created specifically for this purpose.

Fat should be harvested in a thoughtful and artistic manner that improves the patient's figure; thus it must generally be removed bilaterally and symmetrically unless body contours dictate otherwise. Patients must be advised that fat harvest does not constitute a formal liposuction procedure, however, and that the small instruments used to harvest fat are not capable of making large improvements in body contour.

It is prudent to examine the patient at the first consultation, because thin patients with limited fat stores or patients who have undergone prior liposuction often present significant challenges, and considerable extra time and effort will be required to harvest fat from them. Anesthesia and operating times and the surgeon's fee must be calculated accordingly.

Fat is harvested after anesthesia is initiated, but before preparation of the face. In all but the unusual case, complete preparation of the torso is not necessary. Typically, a limited preparation of the marked area is made, and a sterile field is established about the prepared area with adhesive-edged blue paper drape towels (sticky blue towels). The surgeon and the surgical assistant need not gown for this part of the procedure, because sterile gloves are adequate for maintaining sterile technique.

If fat is to be harvested from the hip or lateral thigh, the patient is turned to a semi-lateral decubitus position; preparation, draping, and fat harvesting are performed, then the patient is turned to the opposite side, where the harvest procedure is repeated. If the patient is positioned carefully, this technique can be used to harvest fat from multiple additional sites, including the upper buttocks, inner thigh, and knees. Obtaining fat from multiple sites is particularly important in thin patients with minimal fat stores.

Areas from which fat is to be harvested are conservatively infiltrated with 0.1% lidocaine with 1:1,000,000 epinephrine solution using a specially designed multiholed local anesthetic infiltration cannula, and an adequate time is allowed for a proper anesthetic and hemostatic effect. It is not necessary or desirable to infiltrate in a tumescent fashion, since overwetting the donor site will result in an overdilute harvest and more time being spent in the harvesting process. Local anesthetic should be injected, even if deep sedation or a general anesthetic is used.

Fat is then harvested with special harvesting cannulas attached to 10 cc Luer-Lok syringes; the cannulas are used to atraumatically extract fat from donor sites using gentle hand-applied suction to avoid vacuum barotrauma to the tissue. If fat is harvested with too much applied suction, poor graft survival and compromised outcomes are likely. In general, a 30% to 50% overharvest is made to be sure that an adequate supply of processed fat will be available for use on the face. Fat harvested with these cannulas easily passes through injection cannulas as small as 0.7 mm. Shown from the top down: a 10 cc Luer-Lok syringe, a 1.6 mm by 15 cm local anesthetic infiltration cannula, a 2.4 mm by 15 cm Tulip “triport” harvesting cannula, and a 2.4 mm by 15 cm Coleman harvesting cannula. A closeup of instrument tips, shown from the top down, includes a 10 cc Luer-Lok syringe, an infiltration cannula, a Tulip harvesting cannula, and a Coleman harvesting cannula.

Once the fat harvest is complete, the stab incision used to obtain the fat is closed with a simple interrupted suture of 6-0 nylon. The harvest site is then washed free of prep solution, and the sutured site is dressed with a Tegaderm dressing.

Processing Harvested Fat

Harvested fat is generally not uniform in character and concentration as extracted from the donor sites: each syringe will contain a variable amount of fat, blood, local anesthetic, and ruptured fat cells (oil), and some type of processing is necessary to consistently obtain uniform, viable material for injection. Although fat can be separated simply and inexpensively from the oil and water fractions using a tea strainer type of sieve, the majority of the stem cells, growth factors, and “cellular messengers” are likely lost when this is done. Centrifugation, on the other hand is believed to allow separation of the oil and water fractions from the fat cells with minimal loss of these other potentially important components. In fact, currently efforts are underway to develop low-cost devices for use in clinical settings to process fat in a way that concentrates stem cells, or even allows them to be separated. As these devices become available, the outcomes of fat injection procedures could be significantly enhanced, and many new and beneficial uses of autologous fat will likely become possible.

Controversy exists as to whether the forces applied to the fat during centrifugation are harmful and decrease eventual graft take. Available evidence seems to indicate that the spin speeds and resultant applied forces in most countertop laboratory centrifuges typically sold and used for processing fat are at or below the cut-off value, but surgeons concerned with this can use commercially available rheostats to reduce the voltage and lower spin speeds, if desired. It is likely that once unanimity is reached regarding “safe” spin speeds and threshold G forces, centrifuges will be produced that operate below the appropriate cut-off levels.

Before centrifugation is begun, a sterile, disposable plastic Luer-Lok cap is placed on the end of the syringe to keep harvested fat inside it, and the syringe plunger is removed from the syringe barrel. Capped syringe barrels containing unprocessed fat are then loaded into the centrifuge rotor in a balanced fashion and spun for 1 to 3 minutes. Most small, portable centrifuges are inexpensive and have rotors that can be sterilized so that the syringes the fat are in remain sterile and can be handled by the scrubbed surgical team. Others centrifuges have sterilizable tubes that fit into the rotor for this purpose.

A small, portable, countertop centrifuge is shown, as well as a closeup view of the centrifuge rotor being loaded with unprocessed fat in 10 cc syringes. The syringe tip has been sealed with a disposable plastic cap. The removable and sterilizable metal sleeves shown fit into the rotor to keep syringe barrels sterile and allow them to be handled on the sterile field after spinning.

Harvested fat is shown after centrifugation. Three layers can be seen in the centrifuged material: an upper oil layer consisting of ruptured fat cells, a middle layer of intact fat cells, and a bottom layer of blood and local anesthetic.

The often blood-tinged water/local anesthetic component is separated by simply removing the syringe tip cap and allowing it to run out, and the cap is then replaced. The oil fraction is poured off out of the top of the syringe, and neurosurgical cottonoid sponges are placed inside the syringe barrel to wick up the small amount of residual oil.

A test tube rack to hold the syringes greatly facilitates fat processing activities. On the left, the syringes contain unprocessed fat; in the center, syringes contain centrifuged fat. The rack also conveniently holds 1 cc syringes, syringe components, and other equipment used in the fat grafting procedure.

Injecting Fat

After centrifugation and the oil and water fractions have been discarded, the fat tissue obtained is transferred into 1 cc Luer-Lok syringes using a transfer coupling, because proper injection in the very small aliquots needed in the face cannot be made with 3 cc, 10 cc, or larger syringes. A 10 cc Luer-Lok syringe, 1 cc Luer-Lok syringe, Luer-to-Luer transfer coupling, and transfer coupling in use are shown.

Nerve blocks are then performed with 0.25% bupivacaine with epinephrine 1:200,000 local anesthetic solution and adequate time is allowed for proper anesthetic and hemostatic effect. It is typically not necessary to directly infiltrate areas to

be treated with local anesthetic if nerve blocks are performed correctly and sedation is administered.

If patients state that they have had recent hyaluronic acid filler injections (such as Juvéderm or Restylane) in the areas that they want treated with fat injections, it is likely that the presence of the filler will compromise graft survival and the ultimate outcome of the procedure. In these patients, direct infiltration of areas containing filler can be made with hyaluronidase. In most cases, an immediate and almost instantaneous dissolution of the filler will be noted, and fat injections can then be performed.

Once nerve blocks have been administered, 1.2 mm, 0.9 mm, and 0.7 mm cannulas are used to infiltrate fat into the face through small stab incisions in the facial skin in multiple passes, in multiple planes, from at least two separate injection sites while feathering into adjacent areas depending on the area being treated. Injecting from at least two separate injection sites allows “crisscrossing” of cannula passes during graft placement, and helps avert a “row of corn” effect that might result if injection was made from only one site.

As the cannula is advanced, the surgeon feels for tissue resistance, and if resistance is felt, a small injection is made as the cannula is withdrawn. Approximately 0.5 cc or less is injected per pass. This corresponds to 20 passes or more for each 1 cc syringe of processed fat. If the injector does not feel tissue resistance as the injection cannula is advanced, this indicates that a pass has already been made in that area, and injection should *not* be made as the cannula is withdrawn.

The goal is to inject the fat in a way that optimizes its chance of developing a blood supply and surviving. The injector should have a mental model of scattering tiny particles of fat into the recipient site in multiple crisscrossing fine trails in multiple planes in such a way that each particle ideally sits in its own compartment and has maximal contact with perfused tissue. If fat is injected in the way in which a flu shot would be given or nonautologous fillers are typically administered, fat cells will be bunched together, and only those on the periphery of the injected area will have tissue contact and will be likely to survive. Most of the more centrally situated fat particles will only have contact with each other and will be less likely to survive.

At first the advancement and withdrawal of the injection cannula will necessarily be made slowly, but as familiarity with the technique is acquired, the movements can be made faster. Ultimately, all other things being equal, faster movements are desirable in that if the injection cannula is constantly in motion, intravascular injection is less likely, and an accidental large injection into one area is avoided.

How the syringe is held is also important in controlling the volume injected with each pass, and avoiding overinjection of any area. If the syringe is held in the manner one would typically use to give an injection with the thumb on the end of the syringe plunger, it is easy to inject too much fat if tissue resistance suddenly changes. More control can generally be maintained, and overinjection more easily avoided, if the syringe is held with the end of the plunger in the palm of the hand. Although a bit of practice is required at first, when held this way a slight closing of the hand results in only a small amount of fat being expressed from the cannula.

Although cannula obstruction will be very uncommon if fat is harvested and processed as described, *if a cannula becomes blocked, additional injection pressure should not be applied*, because this is the most common cause of a sudden and unintentional overinjection. It is better to simply withdraw the blocked cannula, pass it to the surgical assistant, and continue with a different one. The assistant can then clear the obstruction while the surgeon continues to work.

Injections will necessarily be made in different planes, depending on the areas being treated. In many areas where multiple tissue layers are present to inject and overlying skin is thick, injections can be made comprehensively at the treated site from the periosteum to the subdermal layer. These areas typically include the geniomandibular groove, piriform aperture, midface, cheek, and chin. These are the easiest areas for the beginning injector to treat. In other areas, injections must be placed with greater precision, skill, and care because of the anatomic characteristics of the treated sites and to avoid irregularities. These areas include the temples, upper and lower orbit, tear trough, lips, jawline, and the dorsum of the hand. In the beginning it is wise to “stay deep” and place the majority of the graft in a predominantly preperiosteal plane. Once the injector is familiar with the technique, areas in the second category can then cautiously be treated.

Fat Injection Instrument Set			
Number	Instrument	Diameter (mm)	Length (cm)
Harvesting			
2	Multihole local anesthetic infiltrator	1.6	15
2	Harvesting cannula	2.4	15
	10 cc Luer-Lok syringes		
	Luer-Lok disposable plastic syringe caps		
Fat Processing			
2	Luer-Lok anaerobic transfer coupling		
1	Syringe rack		
1	Centrifuge		
Injection: Face			
2	Injection cannula	0.7	4
2	Injection cannula	0.9	5
2	Injection cannula	1.2	6
1	V-dissector 1	1.4	6
	1 cc Luer-Lok syringes		
Injection: Breast and Body			
2	Injection cannula	1.2	8
2	Injection cannula	1.4	8
	3 cc Luer-Lok syringes		

Temple Area

Temporal hollowing is a consistent marker of the fourth decade of life that is readily improved with fat injections. This 45-year-old patient is shown before surgery and 2 years and 4 months after a high SMAS face lift and fat injection to the temples. Fat has also been injected in the upper and lower orbital areas.

Injections in the temples must be made in a predominantly subcutaneous plane, usually from small stab incisions just within the temporal hairline. Injection of the temples is performed with a 1.2 mm cannula, and typically 3 to 5 cc of fat is placed on each side, but occasionally more will be indicated.

In most cases a blunt 1.2 mm injection cannula is preferred to sharper and smaller types. This helps to avoid perforation of the tortuous veins often seen in the temporal area. These larger, blunter cannulas usually bounce off these veins and allow fat to be placed over and around them to conceal them, and this compression and concealment of veins is a significant part of the effect gained when treating the temples and the dorsum of the hand. If a temporal vein is accidentally penetrated during injection despite these precautions and swelling from the leakage of venous blood is noted, pressure is applied on the temporal area for a few moments with a surgical sponge. Typically, after applying uniform and continuous pressure for a few minutes, bleeding stops and treatment of the area can be completed.

Upper Orbit/Upper Eyelid Area

Whether a hollow upper orbit is the result of illness, aging, or an overzealous surgical procedure, it can be filled to produce a remarkable rejuvenation of the upper eyelid, eliminating an unnaturally hollow and elderly appearance sometimes referred to by patients as “nursing home eyes.”

This patient had an unnaturally hollow and elderly ocular appearance after a blepharoplasty performed by an unknown surgeon. The patient is shown after fat injections to the upper orbit demonstrating a healthier, more youthful appearance.

What layers fat should be placed in in the upper orbit (upper eyelid) is a subject of some debate, however, and subcutaneous, suborbicularis oculi, and even subseptal (intraorbital) locations have all been safely and effectively used by various surgeons. For the beginning injector, it is safest to avoid the subseptal area because of the small but not insignificant risk of intraorbital and retrobulbar bleeding and other problems. It is also wise to avoid a purely subcutaneous injection in this area at first because of the extremely thin skin present, and to limit initial injections to a preperiosteal/suborbicularis oculi location. As the injector gains experience, injections can be extended to a subcutaneous plane to obtain a combined filling of the submuscular and subcutaneous areas.

A common misconception in treating the hollow upper orbit is that the fat is needed and should be injected in the preseptal portion of the eyelid itself. Not only would this be difficult and dangerous, it is unnecessary. Volume replacement is more properly and practically restored by placing fat in a preorbital position along the inferior margin of the supraorbital rim, and conceptually the process is best thought of as lowering the supraorbital rim and filling the upper orbital area to push skin that has retracted up into the orbit down onto the preseptal eyelid to create a full and creased upper eyelid. Once one accepts that improvement is obtained by injection of the orbit, and not the eyelid itself, it becomes apparent that larger volumes than might otherwise be expected are required, and in general 2 to 3 cc of fat must be placed in each upper orbit to achieve the improvement typically required. Smaller injection cannulas now available have made injecting the upper orbit easier and more predictable than in the past; they can be advanced more smoothly and accurately through tissues and allow deposition of very small aliquots of fat per pass. Currently a 0.7 or 0.9 mm cannula is preferred, but even smaller cannulas may become available and may provide even better results.

It should always be remembered that when injecting the upper orbit one is working in very close proximity to the eye, and although the injection cannulas are blunt tipped, they are small and easily capable of perforating the ocular globe. Thus two important technical considerations should be observed. First, injection sites should be placed in such a way that the injection cannula will be passed parallel to the globe and the supraorbital rim, not perpendicular to it.

Incision sites and a plan for injecting fat into the upper orbital (upper eyelid) area are shown. Injection of the upper orbital area is performed with a 0.7 or 0.9 mm cannula and fat is placed in a suborbicularis oculi/preperiosteal plane. Typically, 2 to 3 cc of fat is placed in each upper orbit. Directing the cannula toward the globe when injecting the upper orbit is dangerous and should be avoided.

Second, the surgeon should always have his or her index finger of the nondominant (noninjecting) hand held firmly on the inferior margin of the supraorbital rim as cannulas are passed into tissues and injection is made, and this finger should always be kept between the tip of the cannula and the globe. The idea is to position the finger so that the cannula would hit against it instead of penetrating the globe if the cannula is inadvertently misdirected. Having one's finger in this position also gives important feedback as to where the tip of the cannula is and helps the injector place fat as accurately as possible.

Lower Orbit/Lower Eyelid Area

Injecting the infraorbital (lower eyelid) area is in some ways analogous to injecting the upper orbit: there are similar misconceptions about where fat should be placed, similar technical considerations about which tissue layers fat should be injected into, and similar concerns regarding injury to the ocular globe. In addition, as with injecting the upper orbit, the artistic payoff is high if the procedure is carried out correctly.

This patient's lower eyelids had an unnaturally hollow and elderly infraorbital appearance. The lower eyelids appeared long, and there was a distinct line of demarcation between the lower eyelid and the cheek. The patient is shown after a face lift and fat injections to the infraorbital area. There is a smooth transition from the lower eyelid to the cheek, and the patient now has a healthier, more youthful and attractive appearance. The upper orbit, radix, cheek, and nasolabial fold have also been treated with fat injections, and the patient has undergone ptosis correction.

Injecting the infraorbital area corrects the age-related hollowness that lends the face an ill or haggard appearance and "shortens" the apparent length of the lower eyelid. Fat injections produce a youthful, attractive and highly desirable smooth transition from the lower eyelid to the cheek that is generally unobtainable by traditional lower eyelid surgery, fat transpositions, "septal resets," midface lifts, free fat grafts, and other means. As in the upper orbit, fat need not and should not be injected in the pretarsal lower eyelid. Fat should be injected deep in a submuscular/preperiosteal plane until experience is obtained. The technical goal of the procedure should be thought of as raising and building up the infraorbital rim rather than filling the lid itself. And, as in the upper orbit, the volumes required to obtain corrections in the lower orbit are typically more than one might initially expect: 3 to 4 cc is usually necessary to produce the desired effect. Experience has shown, however, that unlike the upper orbit, fat is best and most easily injected *perpendicular* to the infraorbital rim, and while I cannot speak from personal experience, it is my observation that surgeons injecting fat parallel to the infraorbital rim have more problems with irregularities, "lumps" and "bumps," and untoward results.

Injection of the infraorbital area is generally performed with a 0.7 or 0.9 mm injection cannula from injection sites in the midcheek or perioral area. Incision sites and plan for injecting fat into infraorbital (lower eyelid) area are shown. Fat is placed in a suborbicularis oculi/preperiosteal plane. Until experience is obtained, more superficial injections should be avoided. Typically, 3 to 4 cc of fat is placed on each side.

As with the upper orbit, when injecting the lower orbit the surgeon should place the index finger of the nondominant (noninjecting) hand firmly on the inferior margin of the infraorbital rim to protect the ocular globe as cannulas are passed into tissues and injections are made.

As the injection cannula is advanced perpendicular to the orbit and toward the fingertip through infraorbital tissues, the orbitomalar ligament can be felt along the infraorbital rim and the cannula tip is allowed to penetrate it slightly. This important landmark helps guide the injector as to exactly where most of the fat needs to be placed for an optimal result. Typically, after placement of 3 cc of fat in this manner, no resistance will be felt along the course of the ligament, and it is assumed that the multiple passes used to place the graft have effectively released it, further improving the overall outcome. Another guideline for the placement of fat in the infraorbital area is for the surgeon to imagine filling the area in which one might place an infraorbital implant, since the goal of treatment is essentially the same.

It is wise to avoid any subcutaneous injection in the infraorbital area until considerable experience has been obtained because of the extremely thin skin in the region,

and to limit initial injections to a preperiosteal/suborbicularis oculi plane, as recommended previously. As experience is gained, injection can then be extended to a subcutaneous plane to obtain a combined filling of the submuscular and subcutaneous areas. This will produce improved outcomes and can help correct dark circles in the infraorbital area by improving the transmission of light through thin infraorbital skin and masking the darker-colored muscle underneath.

Tear Trough

Where the infraorbital area ends and the tear trough and cheek areas begin is hard to define. In reality, the infraorbital, cheek, and tear trough areas must be treated concurrently and the treated areas will overlap to a certain extent. In addition, it must always be remembered that the ultimate goal of the procedure is to create a youthful and attractive *contour*, not simply to fill a specific area.

Treatment of the tear trough is most easily and best performed using the same incisions used to treat the infraorbital area. Incision sites and plan for injecting fat into the nasojugal (tear trough) areas are shown. Injection of the nasojugal area is typically performed with a 0.7 mm or 0.9 mm injection cannula and fat is placed in a preperiosteal/suborbicularis oculi plane. Until the injector gains experience, more superficial injections should be avoided. Fat can be safely placed subcutaneously despite the very thin skin in this area, and improved outcomes are obtained. Typically, 0.5 to 1.5 cc of fat is placed in the tear trough area on each side, depending on how far inferiorly and laterally the tear trough extends onto the cheek.

Another guideline for the placement of fat in the tear trough area is for the surgeon to imagine filling the area in which one might place a tear trough implant, since the goal of treatment is essentially the same. This patient is shown before and after fat injection to her hollow nasojugal groove (tear trough). Preoperatively it can be seen that she had an unnaturally hollow and elderly appearance. Postoperatively the defect has been filled and a healthier, more youthful appearance is evident.

Cheek

Treatment of the cheek is usually performed using access incisions on the cheek and the perioral areas. Injection of the cheeks is performed with a 0.9 mm or 1.2 mm injection cannula, and fat is placed in all tissue layers between the periosteum and skin. Typically, 3 to 7 cc of fat is placed in each cheek, depending on the degree of atrophy present, but occasionally more will be indicated.

Often an asymmetrical placement of fat will be required on the right and left sides, because malar asymmetry is seen in many patients. Another guideline for the placement of fat in the cheek area is for the surgeon to imagine filling the area in which one would place a cheek implant.

As the cheek atrophies, the lower eyelid “fat bags” become more exposed and prominent. Removing lower eyelid fat would create a hollow, elderly appearance. This patient presented with an atrophic cheek, and the lower lid fat was exposed. Seen after fat injections to the cheeks, the patient’s protruding lower eyelid fat has been disguised by building up the cheek; this has produced a more youthful, fit, and attractive appearance than removing lower lid fat would have. The upper orbit has been replenished with fat grafts as well.

Nasolabial Injection

One of the first areas most patients inquire about when considering fat injections, and most surgeons are eager to treat, is the nasolabial folds. Nonetheless, one must be aware of certain misconceptions and several limitations of the fat injection technique in regard to the treatment of this area. The first is that treatment of the nasolabial folds with fat is generally not as effective as treatment with nonautologous fillers. Fat is softer and is typically placed deeper than nonautologous fillers, and fat is better used to treat a volume deficiency in a region of the face as opposed to a more discrete line, wrinkle, or fold that is subject to the repeated stress of facial muscle contraction and facial movement. Patients undergoing fat injections solely for treatment of their nasolabial folds will generally be disappointed with the outcome. However, this is not the case when a concurrent face lift is performed, with cheek and midface tissues repositioned and redundant cheek skin excised. In such instances, fat injection is an excellent adjunct in the treatment of the nasolabial fold (see the patient on p. 1650). It is also not intuitively obvious, but increasingly it is more widely appreciated by those injecting nonautologous fillers into the face that *filling the upper cheek produces a profoundly beneficial effect on the nasolabial fold*, and that treatment of the fold is more effective when filling of both these areas is combined. If the cheek is filled, less fat is needed to improve the nasolabial fold.

This patient had midface ptosis and heavy nasolabial folds; a high SMAS face lift was performed, with fat injections to the nasolabial creases. The combined lifting and filling provided a better correction than either procedure would have if performed alone.

Experience has shown that nasolabial folds result, at least in part, from age-related loss of maxillary projection, and the goal in injecting fat in the nasolabial areas should be thought of as more of an augmentation and restoration of maxillary/midface projection than as simple filling of the soft tissue crease. Thus the surgeon's efforts should be concentrated on the peripiriform areas, and injections should be placed predominantly along the rim of the piriform aperture in the upper nasolabial area.

Injection of the piriform and nasolabial crease is performed with a 0.9 mm or 1.2 mm injection cannula and fat is placed in all tissue layers between the periosteum and skin using access incisions in the perioral area. Typically, 2 to 3 cc of fat is placed in the piriform/nasolabial area, depending on the degree of the problem present, but occasionally more will be indicated.

Another guideline for the placement of fat in the piriform area is for the surgeon to imagine filling the area in which one would place a perinasal or piriform implant.

Overfilling the nasolabial area is a common eventual response when a surgeon feels frustrated upon treating the nasolabial crease with fat in the same manner in which nonautologous fillers would be injected. Higher and higher volumes may be tried in

a typically futile effort to efface the fold, but the crease will not be improved; instead, an abnormally heavy and unaesthetic fullness of the midface will be produced. In addition, overfilling the nasolabial area can produce changes in the position of the patient's mouth, the shape of the smile, and a change in the overall "look." For these reasons it is important to advise patients accordingly, for the surgeon to set reasonable goals, and to limit the amount of fat placed in the nasolabial area to a reasonable amount.

Lips

Treating the lips with fat grafts has distinct advantages and disadvantages that will both attract and repel surgeons and patients alike. Fat is autologous and is arguably like the tissue that was present at a younger age, and if the procedure is successful and graft take is good, patients will be spared the inconvenience and discomfort of having to undergo repeated painful and expensive treatments. Fat also produces a soft, natural-appearing improvement, and usually a slight undercorrection that I find to be most appropriate and even desirable for the typical face-lift patient who needs some enhanced volume in the mouth. In fact, overcorrection of the lips with fat injections, in my experience, is nearly impossible, unless patients undergo multiple treatments.

Fat injections produce soft, natural-appearing lips. Nonautologous fillers invite overcorrection and tend to produce a more stylized-appearing lip. The perioral area of this face-lift patient is shown before fat injections and after a face lift that included fat injections to the lips. The lips are fuller, but soft and natural appearing.

Fat injections to the lips have a distinct disadvantage in that they usually produce a "monstrous" amount of swelling that is slow to resolve; also, the take of the graft varies from patient to patient, and thus the eventual outcome is variable. Patients seeking a quick recovery, a specific lip size or shape, or nuanced changes are not good candidates for a fat injection procedure. In particular, patients must be warned that when using fat, it is generally not possible to create the highly stylized "stung by a bee" or "cover girl" lip appearance seen in fashion magazines. Such an appearance can only be obtained using nonautologous fillers, and patients seeking such appearances should be advised accordingly.

Patients seeking nuanced changes in their lip appearance are also not good candidates for fat injections. These include patients seeking corrections of small asymmetries, patients seeking accentuation of the vermilion-cutaneous junction, or who request specific parts of their lip be “lifted,” “rolled out” and the like. Although fat can be placed to achieve these appearances to some degree, it rarely is dramatic enough to satisfy most patients requesting these sorts of improvements, and patients making these kinds of requests are currently best treated with nonautologous fillers.

When the lips are to be treated, the preparation of the face should include the upper and lower gingivobuccal sulci, the buccal surface of the anterior teeth, and the tongue if it rests in the surgical field anterior to the incisors. A 0.7 or 0.9 mm cannula is usually used to infiltrate fat into the lips, but a slightly larger 1.2 mm cannula may be easier for the beginning injector, since it is harder to accidentally perforate the mucosa or vermilion with the larger instrument. Injection is made from access incisions in the perioral region, and fat is generally infiltrated through all layers of the lip.

Fat is usually placed in submucosal and intramuscular planes. Typically, a total of 1.5 to 2 cc is placed in each side of each lip, for a total of 3 to 4 cc per lip. Smaller amounts generally produce suboptimal outcomes after the initial swelling has abated. Larger amounts increase swelling but generally do not result in an improved outcome.

The first few passes of the cannula are used to place fat subcutaneously or submucosally directly under the vermilion-cutaneous junction. Fat is then infiltrated into the lip muscles, and then beneath the dry lip vermilion. If maximum lip protrusion is desired, fat is placed submucosally beneath the wet mucosa of the inner aspect of the lip.

A common error when injecting fat (or nonautologous filler) into the lips is to indiscriminately fill the lips in such a manner that a large but shapeless and unnatural-appearing “sausage lip” is produced. To some extent the fat injection technique is not prone to this, because lips treated with fat naturally tend to assume the shape of the patient’s existing lip envelope once the swelling abates and healing is complete. An attractive lip is generally one that is not just big, however, but one that has an aesthetically pleasing shape, and fat can and should be injected in a way that creates these appearances. An attractive lower lip typically has two tubercles; that is, two areas of fullness laterally, with a slight central depression between them. An attractive upper lip, on the other hand, has three aesthetic tubercles, a central one and one on each side laterally, with slight depressions between them. The time taken to inject fat to create a natural and aesthetic appearance in these tubercles is well spent. In addition, depressions between lip tubercles can be enhanced on completion of injections by placing a finger and thumb on the inside and outside of the lip and gently bidigitally compressing areas between tubercles to optimize fat position and lip shape.

The second common mistake when injecting the lips with either fat or nonautologous fillers is to make the upper and lower lips the same size. This is an unnatural situation and produces a “clown mouth” or “Halloween wax lips” appearance. In an aesthetic, natural-appearing mouth the lower lip is distinctly larger and fuller than the upper lip, and this should be the goal when augmenting the lips.

Perioral Area

Yet another important use of perioral fat injections is for the treatment of a patient with perioral wrinkles and “pucker lines.” Traditional resurfacing by peel, laser, or dermabrasion typically provides an incomplete solution for these patients in that these procedures only address the skin itself, and do nothing to replenish the age-associated loss of perioral subcutaneous fat. Patients have smoother-appearing skin in repose after these treatments, but when they speak or move their mouth, deep and objectionable lines appear and perioral deflation and subcutaneous atrophy becomes evident. This appearance spoils an otherwise excellent face-lift result and stands as telltale evidence that the patient is really older than she or he otherwise appears. With fat injections this can be avoided, and the fat previously situated between skin and orbicularis oris can be replaced. A second likely but as yet unproven benefit of perioral fat injections rests in the stem cell effect the procedure probably provides.

Experience with combined dermabrasion or laser resurfacing and perioral fat injections suggests that healing and the overall outcome are better when resurfacing procedures are combined with fat injections, beyond the improvement gained by simple added volume.

This woman had a wrinkled, atrophic perioral area that gave her an unhealthy, elderly appearance. She is shown 2 years and 7 months after a high SMAS face lift that included combined perioral fat injections and perioral dermabrasion. Both atrophy and wrinkling have been improved, and the mouth has a more youthful, vibrant, healthy appearance. The combined treatment produced a better appearance than either procedure would have if performed alone.

When injecting the perioral area, care must be taken to not simply overfill the white roll of the upper lip to reduce wrinkles, because the patient's upper lip can be lengthened, dental show can be reduced, and an abnormal, convex, simian contour in profile can result. A better strategy is to concentrate injections on and near the white roll, where the wrinkles are typically the deepest and most objectionable. Less fat is then placed more superiorly. Results are further enhanced by injecting additional fat at the columellar-labial angle, which helps to restore a youthful transition from the nose to the lip and helps to create a concave upper lip shape. Injection in the perioral area is necessarily made with small (0.7 to 0.9 mm) injection cannulas in a subcutaneous/premuscular plane. Placing the fat deeper and intramuscularly is not helpful in creating the type of improvement needed in this area.

Geniomandibular Groove

Injection of the prejowl/geniomandibular groove area with fat has a high aesthetic payoff and is a good area for the beginning injector to gain experience with the technique. Although not immediately intuitively obvious, filling the geniomandibular groove creates a strong, uninterrupted aesthetic line from chin to the posterior mandible, and is a highly desirable improvement on both the male and female face. The effect is similar to the placement of a Mittleman prejowl implant but is autologous and arguably simpler to perform.

This patient had a deep geniomandibular groove. Her chin appeared narrow and pointed, and there was poor continuity between the chin and jawline. She underwent a face lift with injection of fat to fill the geniomandibular groove (prejowl sulcus) area. A chin implant was not placed. Postoperatively the chin appears broader and more aesthetically integrated with the jawline. Fat was also used to strengthen the posterior jawline and lower the mandibular angle, and to fill the lips, nasolabial crease, cheeks, and infraorbital areas.

Injection of the geniomandibular groove is typically performed with a 1.2 or 0.9 mm injection cannula from injection sites on the mandibular border and the perioral area and fat is placed in all tissue layers between the periosteum and skin. Typically, 1 to 3 cc of fat is placed in the geniomandibular groove, depending on the size of the depression present, but occasionally more will be indicated. Another guideline for the placement of fat in the geniomandibular groove area is for the surgeon to imagine filling the area in which one would place a prejowl implant.

Chin

Injecting the chin with fat can enhance a patient's profile and approach the kind of improvements obtained when small chin implants are placed. This patient had an underprojected chin that was also atrophic and feeble looking from the shrinkage that occurs with age. She is shown after a secondary face lift, with fat injections to the chin and geniomandibular groove (prejowl sulcus). A chin implant was not placed. Fat was also injected in the upper and lower orbits, cheeks, lips, and jawline. The fat injections have broadened and strengthened the contours of her chin and jawline, and the submental crease has been filled. Typically, the chin must be treated in conjunction with correction of the geniomandibular groove, and the two areas will overlap each other in most cases. Treatment of the chin along with the geniomandibular groove and jawline areas strengthens the entire lower facial contour.

Injection of the chin is typically performed with a 1.2 or 0.9 mm injection cannula from the same injection sites on the mandibular border and the perioral area used to inject the geniomandibular groove. Occasionally a third incision is used in the midline of the lower lip. Fat is placed in all tissue layers between the periosteum and skin. Typically, 1 to 3 cc of fat is placed in each side of the chin, depending on its size and shape and the degree of atrophy, but occasionally the need for more fat will be indicated. Another guideline for the placement of fat in the chin area is for the surgeon to imagine filling the area in which one would place a “extended anatomic” chin implant.

Despite the suggestions of some to the contrary, fat injections to the chin are best used for small augmentations only. If large changes in chin projection are attempted with fat injections, a globular and less sculptural appearance usually results. Patients in need of larger increases in chin projection are arguably better treated with a chin implant.

Jawline

Injection of the jawline border area with fat can enhance a patient's facial shape and produce the kind of improvements obtained when mandibular border and Taylor-style mandibular angle implants are placed. This patient is shown before surgery with a small mandible, narrow intergonial distance, and lower facial disproportion. The patient is shown after high SMAS face lift and fat injections to the posterior jawline. No implants have been placed. Strengthening the jawline and posterior mandibular border results in a more fit and proportionate appearance, and helps avert the tight and deficient mandibular contour typically seen in an elderly face after a face lift is performed. Fat has also been injected in the chin, geniomandibular grooves, buccal recess, and lip areas. (See also the patient on p. 1626, whose jawline was broadened without implant placement, using only fat injections.)

Injection of the jawline is typically performed with a 1.2 mm injection cannula from the same injection sites on the perioral area and mandibular border used to treat the geniomandibular groove, and fat is placed predominantly in a preperiosteal position. Typically, 3 to 6 cc of fat is placed in each side, depending on the deficiency present, but occasionally 7 to 10 cc or more on each side will be indicated.

Although not intuitively obvious, strengthening the jawline and posterior mandibular border makes one appear more youthful, fit, and attractive and is an artistically powerful adjunct to a face lift. This helps to avert the scrawny, deficient, and fragile mandibular contour typically seen in an aging and elderly face, which is usually made worse when a face lift only is performed (see the patient examples on pp. 1669 and 1670).

Fat injections to the jawline are particularly useful in a secondary face-lift patient and in a patient with a long face seeking facial rejuvenation or improvement. Typically, the secondary face-lift patient has experienced significant loss of jawline volume as a result of loss of or inappropriate surgical removal of facial fat, and this is often compounded by overzealous tightening of the overlying tissues. These appearances are readily improved with fat injections to the jawline, and these form a major part of most of my treatment plans for my secondary and tertiary face-lift patients. A patient with a long face usually will benefit in a similar way, because face-lift procedures tend to narrow the lower face and accentuate facial length. Fat injections allow the face to be broadened, and the overall proportions are improved.

This patient had a small mandible and a long face. A previous face lift performed by another surgeon had tightened the mandibular line and accentuated her facial length. The patient is shown after fat injections to the jawline, chin, cheeks, midface, buccal recess, and lip areas. No implants were placed. The long appearance has been improved, and a more balanced and proportionate look has been obtained.

Final Touches

Injections are continued until the desired volume of fat has been added to target areas. Typically, a twofold to threefold overcorrection must be made compared with the volumes one would use if nonautologous fillers are used. As such, the process is time consuming and technically and artistically demanding, and its difficulty should not be underestimated. That said, it is likely it will also become an enjoyable one that will yield great benefits to patients.

After fat has been infiltrated, treated areas are palpated to ensure that the fat has been distributed smoothly and evenly in the target tissue, and any lumps or irregularities are gently pressed out. The lip and cheek areas can be bidigitally palpated after injection is complete to ensure that fat has been placed in an even distribution, and if the orbits have been treated, the ocular globe should be gently depressed and any irregularities sought in the infraorbital area.

Microliposuction

The face undergoes a process of lipodystrophy over time; the aging deformity consists not only of atrophy, but also of excess fat accumulation in some areas. When indicated, fat can be *extracted* from areas where excess is present by applying suction to an infiltration cannula attached to a 3 cc Luer-Lok syringe. This microliposuction technique provides a simple, precise way for removing small quantities of fat. The amount of fat extracted can be determined by emptying the contents of the syringe on a gauze sponge and allowing the blood and fluid to separate from the fat that has been removed. On the right is the fat extracted from the patient's jowl area; on the left is fat extracted from the nasolabial fold.

Documenting What Was Done

A member of the operating room team should keep a detailed record of areas treated and the amounts of fat injected in each; a Fat Injection Treatment Record is useful for this purpose. Typically, a mark is entered on the record by the circulator for each 1 cc syringe injected.

Nurse signature _____ Date _____

If no circulating nurse is present, a copy of this record can also be sterilized and a temporary tally of the fat injected kept by a scrubbed member of the operating room team using a sterile surgical marker. The information recorded can later be transcribed to the patient's official Fat Injection Treatment Record after the procedure has been completed.

Learning the Procedure

The first step in learning the fat injection technique and adding it to one's face-lift procedure is appreciating atrophy as a significant part of the aging process and learning to recognize it. This is more easily said than done and will take some time to master. Then one needs to obtain the needed equipment to properly perform the procedure and learn the basics of the fat injection technique. Once problems have been identified, needed equipment to perform the procedure obtained, and basics of the technique mastered, one must analyze patient problems carefully and budget the appropriate amount of time needed to carry out the procedure in a technically and artistically appropriate fashion. It is wise to make small additions of fat at first to "safe" areas, such as the geniomandibular groove and the cheeks, to gain familiarity with the technique. Less forgiving areas, such as the upper and lower eyelids (orbits), tear troughs, and temples, should be avoided until injection in the safe areas is mastered. Starting out conservatively in this manner will mean that problems, should they occur, will be minor and easily managed. Finally, patients should be followed up carefully, outcomes critically evaluated, and the injector should look for ways to improve technique and perform the next case with increased skill.

Learning the Fat Injection Procedure

Recognize atrophy as part of the aging deformity.
Learn the basics of the fat injection technique and obtain the needed equipment to properly perform the procedure.
Make the needed commitment of time to properly perform the procedure.
Do not underestimate the technical and artistic difficulty of the procedure.
Make small additions at first to gain familiarity with the technique.
Critically analyze outcomes.
Constantly seek ways to improve your technique.

Completion of Concurrently Planned Procedures

On completion of the fat injections, other planned procedures are performed to the face, neck, forehead, and upper and lower orbits. Next, perioral dermabrasion and any other adjunctive procedures are done, as indicated. Because the majority of fat is needed and will be injected in the anterior face and other areas that do not overlap the areas dissected in these other procedures, performing them after fat is injected does not interfere with their execution or compromise outcomes.

Dressings

After all planned procedures have been completed and all incisions have been closed, the patient's hair is shampooed and rinsed. No dressing is required or applied. Patients are typically discharged with a hat, scarf, and sunglasses.

Postoperative Care

Most patients undergoing combined face lifts and fat grafting are discharged to an aftercare specialist the first night after surgery with specific written instructions concerning their care. Patients are asked to rest quietly and apply iced compresses to their eyes and other treated areas for 15 to 20 minutes of every hour while they are awake for the first 3 days after surgery, or to use a commercially available thermostatically regulated water-cooled mask. For most patients, edema peaks at about 3 days.

All patients are provided oral analgesics, sleeping pills, antiemetic suppositories, and are instructed to sleep flat on their backs without a pillow. A small cylindrical neck roll is permitted if the patient requests it. This posture ensures an open cervicomental angle and averts neck flexion, dangerous folding of the neck skin flap, and the obstruction of regional lymphatics that inevitably occurs if the patient is allowed to “elevate the head on pillows,” as is commonly recommended. In addition, swelling will drain to the back of the head instead of the anterior neck and submental region in this position, where it is not harmful, is less noticeable, and is more rapidly transmitted away from the head and neck area to the torso when the patient sits upright.

Patients are allowed to take their usual diet as tolerated after surgery but are encouraged to avoid salty and difficult-to-chew foods for several weeks. Patients are asked to abstain from drinking alcohol for 2 weeks after surgery and until they are no longer taking pain pills (acetaminophen included) or sleeping medication. Showering and shampooing are not harmful and are permitted even when drains are in place.

Recovery and Healing

When patients can return to work and their social activities will depend on how aggressively their procedure was performed (how much fat was injected), their tolerance for surgery, their capacity for healing, the type of work they do, the activities they enjoy, and how they feel overall about their appearance. Patients are asked to set aside 2 to 3 weeks, to recover from surgery, and additional time off is recommended before an important business presentation, family gathering, vacation, or like events.

If the patient is doing well and is not experiencing problems, she or he is allowed to return to light office work and casual social activity 9 to 10 days after surgery. It is often wise for the patient to begin with a limited workday and to adjust the schedule thereafter. If a patient's job entails more strenuous activity or physical labor, a longer period of convalescence will likely be required. Patients are advised not to drive for the first 10 days after surgery and until they are feeling well, their vision is clear, and they are no longer taking pain medications.

Patients should avoid all strenuous activity during the first 2 weeks after surgery, including heavy lifting, stooping, straining, and bending forward; they should be informed that aerobic activities and exercise can result in internal bleeding and

hematoma formation. Two weeks after surgery, patients are allowed to begin light exercise and gradually work up to their presurgical level of activity. Four to 6 weeks after surgery, they are allowed to engage in more vigorous activities, including most sports, as tolerated.

Patients are informed that it will often take 2 to 3 months to have a natural appearance in a photograph or to be seen at an important function. They are also advised to expect some firmness in the face and submental areas for 6 to 9 months.

Patients will often mistakenly interpret the resolution of swelling and the return of some facial wrinkles as poor graft survival and will often comment once healing is complete that “the fat went away.” Such comments arise out of the joy most patients experience when they see their faces quite full and smooth initially after the procedure and the fact that volume addition to the face often produces subtle three-dimensional changes. Most patients simply forget the extent to which the treated areas lacked volume before the procedure. The treating physician may sometimes initially experience similar disappointment for related reasons; it takes time to train one’s eye to recognize the improvements that have been made. The key to assessing outcomes is to take well-matched photographs in multiple views and to learn to recognize the rejuvenating effects of the injections. Reviewing preoperative photographs with the patient after surgery is an excellent way to assure them that a beneficial improvement has been obtained and that the procedure was productive and worthwhile.

Retreatment

Most of the change in facial contour seen on the patient’s face 4 to 6 months after the procedure is likely to consist of living fat and comprises a persistent improvement. At that point, patients can be told that “what you see is what you get,” because swelling and induration will have almost completely resolved by that time. Four to 6 months after surgery is also the time at which most surgeons performing fat injections think that facial edema, induration, and inflammation have resolved sufficiently that retreatment can be considered if indicated and the patient requests it. Because there is a limit to the amount of fat that can be infiltrated into a thin, atrophic face, the need for secondary fat grafting should not be viewed as a failure of the primary procedure; it is simply an inherent limitation of the technique. If the patient achieved improvement with the primary treatment, a secondary procedure will typically be equally or more beneficial, and often can be far less comprehensive than the first.

Complications

No major complications attributable to fat injections have been seen while performing the procedure concurrent with face lifts, including infection and embolization. However, these problems have been reported and are known to occur when fat injections are performed. To date and to my knowledge, there had been no reports of embolization with blunt-needle injections, but this could change as infiltration cannulas become smaller and more surgeons perform the procedure. Embolization and related complications, including blindness, have been reported with sharp-needle injection; these and other complications of fat injections have been discussed in detail by Coleman.

Complications of simultaneous face lift and fat injections attributable to the fat injection procedure fall largely under the heading of “aesthetic problems” and include lumps, oil cysts, asymmetries, undercorrection, overcorrection, and donor site irregularities. These are more accurately considered inherent risks of the procedure, however, in that even if the procedure is technically performed properly and with care, variations in “take” that can occur with any graft that are beyond the surgeon’s control can cause them. This is particularly true in the case of a fat graft, because fat has shown itself to be a comparatively fragile tissue.

Most complications will be small and easily managed if fat injections are performed properly and conservative additions are made. Oil cysts can usually be simply aspirated or unroofed. Lumps have been exceedingly rare in my practice but are now being increasingly seen in patients treated by other physicians. These can usually be treated by microliposuction, direct excision, or overgrafting with more fat. Asymmetries and undercorrections are generally treatable by additional fat injections and donor site irregularities with touchup liposuction and/or fat grafts. Overcorrection is uncommon in single-stage treatments and is typically seen in patients undergoing multiple fat injection procedures. Overcorrection can usually be improved by judicious extraction of fat from overcorrected areas.

It is best to avoid complications altogether; the surgeons with the fewest are likely to be the ones who take the time to learn to perform the procedure properly, obtain the needed equipment necessary to do so, and introduce it into their practice gradually and in a conservative manner.

Results

This 45-year-old woman had overall facial laxity and panfacial atrophy; she had no previous plastic surgery. She is shown 2 years and 4 months after a high SMAS face lift, neck lift, closed forehead lift, lower blepharoplasty, and fat transfer to the temples, cheeks, lips, nasolabial folds, geniomandibular grooves, stomal angles, and upper and lower eyelid areas (see p. 1630 for an indication of where fat was placed in this patient). A total of 50 cc of fat was placed. Note the soft, natural facial contours and the absence of a tight, pulled, or face-lifted appearance. Facial atrophy has also been corrected, and the patient has a healthier, more youthful, and feminine appearance. The combined face lift and fat injection procedures have produced a result that could arguably not be obtained by either procedure alone.

This 68-year-old man had sagging cheeks, deep cheek folds, and jowls. Loss of facial volume was also evident in his cheeks and infraorbital, perioral, and genio-mandibular groove areas. The patient is shown 1 year and 9 months after a high SMAS face lift, neck lift, closed forehead lift, upper and lower blepharoplasty, partial facial fat injections, and earlobe reduction. A total of 28 cc of fat was placed. A more youthful facial shape has been restored without a tight or pulled appearance. His facial atrophy has also been corrected, and he has a healthier, masculine appearance. The combined face lift and fat injection procedures have produced a result that could arguably not be obtained by either procedure alone.

This 53-year-old woman had facial sagging, and although her face appears full at first glance, a careful examination shows that regional atrophy was present in her temples, cheeks, infraorbital, perioral, geniomandibular groove, chin, and jawline areas. The patient had prior upper and lower blepharoplasties performed by another surgeon. She is shown 1 year and 5 months after a high SMAS face lift, neck lift, temple lift, canthopexy, and fat transfer to the temples, cheeks, infraorbital, nasolabial, perioral, geniomandibular groove, chin, and jawline areas. A total of 66 cc of fat was placed concurrent with the face lift and related procedures. Soft, natural facial contours have been restored, without a tight, pulled, or face-lifted appearance. Her facial shape has been significantly improved, and she now has a more youthful appearance. Although fat has been added to her face, she has a trimmer, more fit, and feminine appearance. Her lips are fuller but natural looking. An unwanted mole has been removed from the left upper lip.

This 75-year-old woman had had multiple prior face lifts and related procedures, including previous laser resurfacing performed by other plastic surgeons. She had significant cheek laxity despite these surgeries, and a fragile, elderly appearance as a result of uncorrected panfacial atrophy. Another face lift would predictably have produced a gaunt, haggard, or even ill appearance. The patient is shown 1 year and 7 months after a high SMAS face lift, neck lift, forehead lift, upper and lower blepharoplasties, canthopexy, and fat transfer to the temples, cheeks, midface, upper and lower eyelids, lips, nasolabial folds, stomal angles, geniomandibular grooves, chin, and jawline. A total of 90 cc of fat was placed concurrent with the face lift and related procedures. No skin resurfacing, facial implants, or other ancillary procedures were performed. In these situations, fat injections are arguably more important to the overall outcome than the face lift itself. Her facial contour has been significantly enhanced and her facial volume restored. The patient has a healthy, fit, more youthful, and feminine appearance—one that could not be obtained by either procedure performed alone.

Clinical Caveats

Patients with significant *facial atrophy* will generally achieve suboptimal improvement from both surface treatments of facial skin and surgical lifts. The addition of fat to areas of the face that have atrophied from age or disease can produce a significant and sustained improvement in appearance that is unobtainable by other means.

Performing fat injections in conjunction with a face lift has certain disadvantages that must be acknowledged, including the learning curve associated with any new procedure, an increase in operating room time, increased postoperative edema, a longer period of recovery, and uncertainty of graft take.

Fat contains adult stem cells that are believed to elaborate growth factors and other as yet not clearly defined cellular mediators that appear to have a regenerating effect on adjacent tissues, and it is likely that injecting fat into the face as part of a face lift has a rejuvenating and regenerative effect on the facial skin.

Isolated fat injections are of questionable benefit to a patient with significant facial sagging and skin redundancy. Although aggressive filling of the sagging face with fat can improve contour and produce a smoother skin surface, it generally results in an unusually large, overfilled face that appears both unnatural and unfeminine.

Areas in need of treatment with fat will vary from patient to patient, and planning fat injections requires looking at the face more as a sculptor and less as a tailor, as we have done in the past.

Poor outcomes are typically obtained if sharp hypodermic needles are used to harvest and inject fat, and if fat is injected in a manner similar to that used to inject nonautologous facial fillers. Sharp needle injection can also result in fat embolization and serious related problems and is not recommended.

Donor sites are typically chosen in conjunction with the patient to improve his or her silhouette, although ideal locations are arguably those areas of diet- and exercise-resistant fat collections where the fat is biologically programmed to persist throughout the patient's life.

Donor sites and site markings should be photographed preoperatively to document what was agreed on and to avoid any dispute over the patient's preoperative condition after surgery.

Fat should be harvested in a thoughtful and artistic manner that improves the patient's figure. Thus it must generally be removed bilaterally and symmetrically, unless body contours dictate otherwise.

Continued

Clinical Caveats—cont'd

Harvested fat is generally not uniform in character: each syringe will contain a variable amount of fat, blood, local anesthetic, and ruptured fat cells, and processing is necessary to obtain uniform material for injection.

A common misconception in treating the hollow upper orbit is that the fat should be injected in the preseptal portion of the eyelid itself. Volume is more properly restored by placing fat in a preorbital position along the inferior margin of the supra-orbital rim.

When injecting the upper orbit, one is working in close proximity to the eye, and although the injection cannulas are blunt tipped, they are capable of perforating the ocular globe.

Filling the upper cheek produces a profoundly beneficial effect on the nasolabial fold, and treatment of the fold is more effective when combined filling of both these areas is made. If the cheek is filled, less fat is needed to improve the nasolabial fold.

A common error when injecting fat into the lips is to fill the lips in such a manner that a large but shapeless and unnatural-appearing “sausage lip” is produced.

Injection of the geniomandibular groove with fat has a high aesthetic payoff and is a good area for the beginning injector to gain experience with the technique.

Although not intuitively obvious, strengthening the jawline and posterior mandibular border makes patients appear more youthful, fit, and attractive.

It is wise to make small additions of fat to “safe” areas at first to gain familiarity with the technique.

Patients should be followed carefully, outcomes critically evaluated, and the surgeon should constantly seek ways to improve injection techniques.

CHAPTER 48

Neck Lift

FOAD NAHAI

My thinking and current approach to treatment of the neck have been influenced by the work of my close friends. Courtiss's submental liposuction, Feldman's corset platysmaplasty, and Connell's modification of the subplatysmal structures, combined with the experience John Bostwick and I had with endoscopic face and neck lifting, have all shaped my approach to the neck. Equally important has been the experience gained through secondary neck lifts.

Courtiss demonstrated that removal of submental fat resulted in redraping and recontouring of the submental skin without any redundancy. Normal skin quality and elasticity are prerequisites. Feldman's corset platysmaplasty improved the submental contour and jawline and eliminated platysma bands. Connell's subplatysmal approach further improved neck contour through the elimination of bulging fat, digastric muscles, and submandibular glands. Our experience with endoscopic face and neck lifts clearly established that all of the components of a neck lift could be performed through minimal-access incisions, and if skin excision was not needed, the standard retroauricular face-lift incision, serving only for access, could be totally eliminated.

Almost all face-lift procedures, especially those involving the SMAS, will have some effect on the neck, particularly the jawline. For a small group of patients this may be all that they need, whereas others will need more extensive procedures involving a submental incision. I have found the vertical simulation test very useful in my decision-making concerning the need for a submental incision and central neck procedures. Neck lifts are not only performed in conjunction with face lifts, but also as separate procedures without a concomitant face lift.

Not all patients' necks have the same morphology, nor do their necks age at the same rate or in the same way. The approach to each neck is individualized to maximize the result. Neck lifting involves a combination of rejuvenation or reversal of the aging process and recontouring. The spectrum of procedures available to us ranges from

liposuction only to a full open neck lift, and through multiple incisions with intervention in each of the three planes—superficial, intermediate, and deep. After careful evaluation, the surgeon selects the appropriate procedure and plans the incisions, vectors, and planes of intervention.

Surgical Options

Liposuction only	Endoscopic neck lift
– Suction-assisted liposuction (SAL)	Short-scar face lift, with or without submental incision
– Ultrasound-assisted liposuction (UAL)	Full-scar face lift, with or without submental incision
– Power-assisted liposuction (PAL)	
– Laser-assisted liposuction (LAL)	
Submental lift	

The components of a neck lift include fat contouring, muscle and fascia plication, subplatysmal procedures, skin redraping and redistribution, and skin excision. Fat may be removed from under the skin, between the platysma muscles, and below the muscle. In the superficial plane the fat may be removed through liposuction or direct excision. The fat between and deep to the platysma muscles is removed by direct excision, since liposuction deep to the platysma is risky and inappropriate. Muscle and fascia plication involves the platysma muscle and its investing fascia. The procedures deep to the platysma include fat removal, tangential excision of the anterior belly of the digastric muscles, intracapsular removal of the superficial lobe of the submandibular gland, and release of the suprahyoid fascia.

Components of a Neck Lift

Fat contouring	Subplatysmal procedures (deep plane)
– Superficial	Skin redraping and redistribution
– Deep	Skin excision
Muscle and fascia plication	Skin resurfacing

Management of skin in the neck differs from management of facial skin. To obtain optimal results in the neck, it is not always necessary to remove excess skin. The neck affords more options for skin redraping and redistribution, and excellent results are possible without skin excision. The key is to assess the skin of the neck and establish whether the excess, if any, is real or apparent.

Pertinent Anatomy

Fat

Within the neck, fat is found in the subcutaneous tissue between the skin and platysma muscle. The thickness of this fat pad will vary according to the patient's morphology and weight. It is usually more abundant in the submental area, extending in between the platysma muscles if they are separated at this level. There is also a collection of fat deep to the platysma muscles and superficial to the digastric muscle and the submandibular gland. Dramatic neck recontouring can be achieved through removal of neck fat in these different levels.

This operative view demonstrates en bloc resection of preplatysmal-submental fat and separate en bloc resection of interplatysmal and subplatysmal fat.

Although the jowls or the jowl–fat pads extend into the neck, it is facial fat that should be returned to the lower face where it belongs, or be excised as needed. It is not part of the fat in the neck.

Muscle

The platysma muscles separate the neck into superficial and deep compartments. The muscles are large, thin sheets that extend from the face across the neck and down to the clavicle. Within the submental area the anatomy of the muscle varies greatly from individual to individual.

Cardoso de Castro's anatomic studies led him to classify the relationship of the two platysma muscles and their interdigitations or decussation in the submental area into three types.

This confirms our clinical impression that in the majority of patients there is very limited interdigitation of the muscles medially, as evidenced by the two visible platysma bands in the aging neck. Stuzin discussed retaining ligaments that hold the platysma against the deep cervical fascia; he described them as a series of fibrous bands extending from the mandibular symphysis distally to the thyroid. With aging, attenuation of this retaining ligament system allows platysmal descent, which accounts not only for platysma bands but also for the increasingly oblique cervical angle, both hallmarks of the aging neck.

Digastric Muscle

The anterior belly and posterior belly of the digastric muscle form two sides of the submental triangle. The third side is the ramus of the mandible. Within this triangle lies the submandibular gland, facial artery and vein, the lingual nerve, and the marginal mandibular branch of the facial nerve.

Submandibular Gland

Submandibular glands lie within the submental triangle. Whether clinically visible glands are protic or simply enlarged is currently a matter of debate. The submandibular gland lies in close proximity to the facial artery, which crosses superficial to the

posterior portions of the gland. The marginal mandibular branch of the facial nerve crosses the gland superficially. The safest approach to resection of the gland is intracapsular, because all of these structures lie outside of the capsule of the gland.

Clinical Correlations

The platysma divides the neck into a superficial and deep compartment. My clinical approach to the neck, the layered approach, includes intervention in three planes: superficial, intermediate, and deep.

The superficial plane includes only the subcutaneous fat, and intervention in this plane is limited to fat contouring.

The intermediate plane includes the platysma and any fat lying between the two muscles and the occasional lymph node. Intervention in this plane includes resection of the fat and plication of the platysma muscle medially and laterally. The deep plane includes the subplatysmal fat, the digastric muscles, and the submandibular gland. The resection of the subplatysmal fat is relatively safe; however, the anterior veins of the neck may course within the fat.

Tangential excision of the anterior belly of the digastric muscle is also relatively safe and bloodless. The dissection of the submandibular gland has to be performed cautiously and within the capsule. Resection of the superficial lobe is relatively safe, because this portion of the gland is well away from the facial vessels, facial nerve, and lingual nerve. Dissections beyond this superficial lobe or extracapsular dissection of the gland are more likely to lead to vascular injury with profuse bleeding and nerve injuries. The suprahyoid fascia also lies in the deep plane. This fascia is occasionally released to further improve on the cervical angle in patients with a high hyoid.

Preoperative Assessment

Careful evaluation of the neck and its relationship to the lower third of the face will lead to selection of the appropriate procedure to meet the patient’s goals. This evaluation also helps to determine incisions, vectors, and planes of intervention. In order of importance in neck recontouring and rejuvenation, I assess the fat, muscles, submandibular gland, and finally, the skin for skin excess and skin elasticity. The jowls and the jawline, the interface of the neck and face are also evaluated.

Focus of Neck Evaluation	
Fat	Skin
Muscles	Neck-face interface
Submandibular gland	

Fat removal has the most dramatic effect on neck contouring. Therefore it is important to determine the accurate location of fat in the neck, whether it is only under the skin or also between and below the platysma muscles.

Evaluation of the location of submental neck fat, pinching the submental area at rest

Subcutaneous versus subplatysma fat is assessed by pinching the submental area during contraction

To differentiate between subcutaneous and subplatysmal fat, the surgeon pinches the submental area with the patient at rest and then after contraction of the platysma muscle. If the amount of fat within the pinch diminishes on contraction of the muscle, a significant amount of fat lies deep to the muscle, indicating that subcutaneous fat removal alone may not result in an ideal contour. If there is subplatysmal fat, an open procedure for defatting below the platysma is indicated, and subcutaneous fat removal or liposuction will yield a suboptimal result.

Evaluation of excess skin of the neck and platysma bands with the patient at rest

Evaluation of platysma bands on animation

The platysma and digastric muscles are evaluated. The platysma bands may be visible at rest or on animation only. The location of the bands and the distance between them is noted. Transcutaneous evaluation of the digastrics may not always be possible, especially in a heavy neck. The digastric muscles are best evaluated during the procedure, after the subcutaneous fat is removed.

If flexion of the neck results in a bulge, it may be appropriate to consider digastric muscle excision. Occasionally the digastric muscle may be visible transcutaneously, especially in candidates for a secondary neck lift. The submandibular gland is often visible transcutaneously, presenting as a bulge within the submental triangle. In a heavy neck it may not be visible, and intraoperative evaluation may be necessary before the surgeon decides about the gland.

Skin

The length of the skin incision in neck lifting reflects the location of the excess skin to be removed. If there is no excess, the entire neck procedure is performed through minimal incisions. I evaluate whether the skin excess is real or apparent, and if it is real, where that excess lies. The success of short-scar procedures relies not only on

assessment of the location of skin excess, but also on the quality and elasticity of the skin. The vertical simulation test is invaluable in evaluating skin quality and skin excess. Normal skin elasticity is essential for all short-scar procedures. Patients who have inelastic, sun-damaged skin must have the full retroauricular incision for a good result.

Apparent excess skin will redrape after recontouring below the skin, such as submental skin following fat removal in all three planes, as well as digastric and submandibular gland excisions. The skin must have sufficient elasticity to redrape. It is the long side of the triangle redraping into the two shorter sides, thus eliminating the apparent skin excess.

Skin redraping is shown after fat removal and platysma plication through a submental incision. A short preauricular incision was made to tighten the SMAS to improve on the jowls and the jawline. No neck skin was excised.

Real excess skin usually extends below the thyroid cartilage and posteriorly beyond the sternocleidomastoid muscle. If there is real excess skin or if skin quality is poor, a full retroauricular incision is essential.

This patient demonstrates skin excess beyond the thyroid cartilage and behind the sternocleidomastoid muscle, as well as poor skin elasticity, as evidenced by the sun-damaged appearance. A full face-lift incision, including a retroauricular extension, is required for an optimal result.

Vectors

Skin evaluation influences my choice of vectors. The vertical vector applied to the neck in combination with a face lift, through SMAS and skin elevation, will define and improve the jawline. The more diagonal vector required for skin resection in the retroauricular area will define and improve the lower and lateral neck.

Neck-Face Interface

If there is significant jowling and descent of the neck-face interface, an isolated neck lift procedure will not address that problem and will lead to a suboptimal result. In such patients a lower face and neck lift is a more appropriate operation. In selected patients, judicious liposuction of the jowl fat will improve the jawline.

Planes of Intervention

Through clinical evaluation of the neck I determine the planes of intervention. If only subcutaneous fat excision is needed, liposuction in the superficial plane would be the procedure of choice. If platysma bands have to be dealt with, an intermediate plane intervention is planned. If subplatysmal fat removal, modification of the digastric muscles, or submandibular gland excision are required, intervention in the deep plane is planned. It is not rare to perform procedures in all three planes.

OPERATIVE TECHNIQUE

Liposuction

The best candidates for liposuction recontouring of the neck are usually younger patients with normal-quality skin and localized excess submental fat. Clinical evaluation of the platysmal muscles and subplatysmal fat is the key to patient selection. In addition to the pinch test described earlier, the patient's neck is examined at rest and on animation for the presence of platysma bands.

Platysma bands visible at rest

No visible platysma bands at rest

Platysma bands visible on animation

If platysma bands are present at rest, the patient would be best served by a submental lift. If bands are visible on animation but not at rest, removal of the subcutaneous fat will expose the bands, and these patients are also best served by an alternative approach that would eliminate the platysma bands. Liposuction will unmask underlying platysma bands or deep plane fullness. The best way to avoid this is a complete and detailed evaluation of the neck before selecting liposuction as the procedure of choice for neck contouring.

Technique

Liposuction of the neck may be performed with the patient under local or general anesthesia. I prefer general anesthesia if additional procedures are planned. The patient is placed supine on the operating table with the neck in full extension. Through an access incision in the submental area and optional incisions behind each earlobe, the neck is infiltrated with a wetting solution. My preference is Ringer's lactate solution with 250 mg of lidocaine and 1 mg of epinephrine added to each liter. I find

that 100 ml of this solution is more than adequate for anesthesia, vasoconstriction, and sufficient wetting of the tissues for UAL. I usually wait 12 to 15 minutes following infiltration for full anesthetic effect and vasoconstriction.

Ultrasound-Assisted Liposuction

For UAL of the neck, I use a short 2 or 3 ml solid probe with a power setting of 5 and either continuous or pulse mode with the LySonix UAL device (Mentor Corp., Santa Barbara, CA). The UAL phase is usually no longer than 2 to 3 minutes. This is followed by aspiration with a flat 2 or 3 ml cannula. I prefer UAL over SAL in the neck, because in my hands it yields a smoother result.

Suction-Assisted Liposuction

My choice of cannula for suction-assisted liposuction of the neck is a flat 2 or 3 ml single-hole cannula. The suction is started through the submental incision with the hole always toward the deep tissue, never toward the skin. It is important to leave at least 3 to 5 cc of fat on the deep surface of the skin to avoid postoperative irregularities. Removal of an excessive amount of fat or oversuctioning under the dermis will lead to adherence of the skin to the underlying platysma, resulting in tethering and banding.

Excessive fat removal in the subcutaneous plane to mask or correct problems deep to the platysma is a common error that is often difficult to reverse, as seen in this woman. Overaggressive fat removal from her neck and submental area has unmasked platysma bands and prominent digastric muscles.

In SAL of the neck the cannula is passed slowly through separate tunnels, fanning out from the submental incision. I make it a point to never make more than one or two passes in each tunnel, because repeated passes within a tunnel will lead to oversuction and irregularities. If suction of the jawline and lateral neck is also indicated, a separate incision behind each earlobe is made for access. This also allows a crisscrossing of the tunnels in the submental area. It is best to err on the side of leaving too much fat behind rather than oversuctioning. The endpoint is judged by direct observation of the recontouring effect and by pinching the skin and subcutaneous tissues. I also roll my fingers along the skin with gentle pressure to look for irregularities to ensure that the fat removal has been uniform.

No drains are required for liposuction of the neck, but compression is applied with either foam tape or an elastic garment.

Results

This patient underwent liposuction of her neck 4 years earlier. The redraping of her excess neck skin in the submental area is apparent. No skin excision was performed.

This young woman underwent UAL of the submental area and neck; she still has some persistence of her jowls, but the jawline and submental area have been improved.

This patient underwent liposuction of the submental area and transoral chin augmentation with a solid silicone implant. Improvement of facial proportions is demonstrated, with a more pleasing jawline and neck-jaw angle.

Liposuction of the submental area and neck unmasked this patient's platysma bands, which are more noticeable on the right than on the left. A better result would have been achieved through a submental neck lift, including platysma plication.

Submental Neck Lift

The submental neck lift includes an incision in the submental area, variable undermining of the neck, and intervention in each plane of the neck as indicated. The submental neck lift may be performed as an isolated procedure for recontouring of the submental area and neck or in combination with a short- or full-scar face lift. The degree of skin undermining will vary from individual to individual, depending on the clinical appearance of the neck, skin quality, and skin excess.

Technique

An isolated submental neck lift is not a common procedure in my practice. The submental approach described here is usually performed in combination with a face lift.

The procedure is performed with the patient under general anesthesia; the patient is placed supine with the neck extended. The neck is infiltrated with a dilute lidocaine and epinephrine solution, usually 0.25% lidocaine with epinephrine 1:400,000. The incision is made just posterior to the submental crease. The dissection is then continued anteriorly under the crease to release it from the underlying tissues. If indicated, this dissection progresses forward and laterally to release the mandibular ligaments. Subcutaneous defatting is then performed. I prefer to do this directly rather than through liposuction. With the scissors, I elevate the skin with a 3 to 5 mm layer of fat.

Extent of undermining laterally varies from patient to patient

The skin is undermined in this plane toward the thyroid cartilage and laterally as needed. Then this submental fat is resected from the superficial surface of the platysma. In thin individuals in whom no fat removal is planned, the dissection starts directly over the platysma, leaving all the fat on the deep surface of the skin.

If procedures are planned deep to the platysma, the platysma on each side is elevated, and any fat in between and deep to the platysma is directly excised as needed. If interplatysmal or subplatysmal fat excision is planned or performed, it is very important to leave an adequate subcutaneous layer of fat to avoid a submental depression. There is often a very small lymph node or two in the fatty layer, between and deep to the platysma, which is usually included in this resection.

Platysma muscle elevated to expose fat and digastric muscle

Once the platysma has been elevated and the fat deep to it removed, the anterior belly of the digastric muscle on each side can easily be visualized. The anterior bellies of the digastric muscles may be tangentially excised, totally excised, or the two pliated in the midline.

Most commonly I do a tangential excision. This starts anteriorly at the origin of the muscle. A hemostat is passed halfway through the thickness of the muscle.

The tips are then spread, and with electrocautery the muscle fibers are transversely divided so that at least half the thickness of the muscle is tangentially excised by dissecting posteriorly along the muscle to its tendinous junction. On the rare occasions when I resect the entire anterior belly, the origin is divided first with electrocautery and then the tendinous junction.

Once the anterior belly of the digastric muscle has been dealt with, an enlarged submandibular gland is easily visualized. Even if a decision has already been made to dissect the gland, the neck is flexed and the contour assessed before proceeding with partial gland excision. The most important step in resecting the gland is to incise the capsule and to perform the resection piecemeal. This will greatly decrease the risk of bleeding and damage to the surrounding nerves.

Once the gland is visualized, I grasp it with an Allis forceps or place a 3-0 suture through the gland and pull the gland into view. The capsule is incised with needle-tip cautery; then the gland is resected piecemeal. If there is any bleeding, the vessels are easily cauterized. Occasionally the small artery feeding the gland is encountered and must be suture ligated. Once the gland has been suitably reduced in size, the neck is again flexed and the effect on neck contour assessed. Gland excision proceeds in this manner until the desired contour is achieved.

Piecemeal excision of superficial lobe
of submandibular gland

After these deeper procedures are completed, the platysma muscles are plicated in the midline. I prefer interrupted sutures with permanent material. The tail end of a suction drain is left deep to the platysma before completing the midline plication. Occasionally I plicate the platysma in two layers. The second layer is sutured with an absorbable material.

For an isolated submental lift, the procedure at this stage is almost complete. Neck undermining extends laterally on either side until effective skin draping is seen. If there is any skin redundancy, the undermining is extended until this excess is eliminated. Any remaining contour irregularities are dealt with through direct fat excision, if possible. Otherwise, liposuction is done with a small, flat 2 or 3 mm cannula. A suction drain is routinely placed in the neck. The skin is closed in two layers—4-0 Monocryl for the dermis and intracuticular 5-0 Monocryl for the skin. Tapes and dressings are applied.

Postoperative Care

Patients undergoing an isolated submental lift may be allowed to go home on the same day as surgery. Those undergoing a face lift in combination will remain overnight in our facility. A compression tape or garment is worn for several days postoperatively. The drain is removed the next day after surgery.

Result

Preoperative evaluation of this man demonstrated platysma bands on animation, with fat superficial and deep to the platysma muscle. He had an indistinct neck-jaw angle. He underwent a submental neck lift, including subplatysmal fat excision and digastric excision. No subcutaneous fat was removed so that a smooth contour remained. He also had chin augmentation with an anatomic solid silicone implant. Postoperative views demonstrate improved contour without skin irregularities.

Endoscopic Neck Lift

Technique

The submental neck lift described earlier has almost entirely replaced our original endoscopic neck-lift procedure. This procedure was essentially the same through the submental incision. Additional incisions were then made behind each earlobe, and the endoscope aided in the wide undermining of the neck skin from one sternocleidomastoid muscle to the other. Endoscopic visualization also facilitated hemostasis. A headlight and a Deaver or lighted retractor through the submental incision have now replaced the endoscope.

Results

This patient underwent an endoscopic neck lift, including platysma plication and neck suspension sutures through a 4 cm submental incision and a 1 cm retroauricular incision on each side. There was no skin excision.

A similar procedure was performed on this patient, who exhibited platysma bands and apparent excess skin in the submental area.

Short-Scar Face and Neck Lift

The ideal candidate for a short-scar face and neck lift is a patient who has no excess neck skin with jowls and aging of the neck-face interface. The short-scar approach, with a vertical upward vector on the SMAS and slight diagonal vector on the skin, will improve the jawline. If needed, neck recontouring through liposuction or through a submental approach may be performed at the same time. With the submental approach, I connect the face and neck dissection in the subcutaneous plane. The technical aspects of the procedure for the neck were described earlier.

Technique

A prehairline incision is made below the sideburn and a preauricular intratragal incision down to and around the earlobe.

The skin flap is elevated and the dissection connected with the neck dissection, which usually extends to the posterior border of the sternocleidomastoid.

The sub-SMAS dissection is then initiated at the junction of the adherent and mobile SMAS. A diagonal incision is made in the SMAS, extending from the zygomatic prominence medially toward the angle of the mandible laterally. The dissection then continues along the lateral border of the platysma.

The SMAS-platysma flap is mobilized by blunt dissection and then pulled upward in the face and posteriorly in the neck. Usually in a heavy face, a portion of the elevated SMAS and platysma is resected; in thin faces, it is plicated with permanent suture material. My preference is 3-0 Mersilene. The lateral plication of the platysma will further define the neck. This lateral plication is always performed regardless of whether a submental approach and medial platysmal plication is performed. I place a drain in all face lifts. The drain is brought out behind the earlobe.

The facial skin is pulled directly upward with a slight diagonal vector posteriorly. The excess skin is resected and an anchoring suture of 3-0 PDS is placed at the base of the concha. The excess skin is then trimmed, tailored around the tragus, and inset. A two-layer closure of 4-0 Monocryl to the dermis and running 6-0 rapid-absorbing catgut to the epidermis completes the procedure. Dressings are applied, and the patient remains overnight in our facility.

Results

This woman underwent a short-scar face lift that included a submental incision with platysma plication. She is seen 4 years postoperatively.

The preoperative views of this patient demonstrate apparent excess skin in the submental area, jowls, and platysma bands on animation. She underwent a short-scar face and neck lift, including a submental incision with submental fat removal and platysma plication. The postoperative view demonstrates neck recontouring, improvement of jowling, and no retroauricular scars.

This ideal candidate underwent a short-scar face lift through a submental incision with subplatysmal intervention, including partial excision of the submandibular gland. A lower lid blepharoplasty was also performed. The postoperative result demonstrates improvement of the submental area and jawline.

Full-Scar Face and Neck Lift

The best candidates for a full-scar face and neck lift are individuals with aging changes of the face and neck, especially the neck-face interface, with inelastic skin and excess lower and posterior neck skin. The vertical simulation test is most useful for selecting short or long scars. The procedure is similar to the operation described previously, with the exception that the skin incision is continued around the earlobe up to the level of the tragus or higher and then across into the occipital hair.

This patient demonstrates jowls, a visible submandibular gland, platysma bands, and excess skin below the thyroid.

The vertical vector on the SMAS will improve her jowls, and the redraping of the apparent submental skin excess will improve the submental area.

With rather long sideburns, this patient is a candidate for the classic face-lift incision, extending from the temporal area into the occipital hair. The postoperative view demonstrates neck recontouring.

Technique

Occasionally, in individuals with unusually lax skin with significant excess skin in the lower neck, this incision is modified so that at the level of the tragus or just below, it will cross to the hairline and follow the occipital hairline downward and posteriorly. This modification allows resection of more of the neck skin without altering the occipital hairline. There is more extensive skin undermining with this incision, extending beyond the posterior border of the sternocleidomastoid muscle and behind the ear. Management of the SMAS and platysma was described previously, as was the anterior closure of the wounds.

A second anchoring suture of 3-0 PDS is placed through the skin flap and into the mastoid fascia at the level of the earlobe. The excess skin behind the ear is resected in stages, aligning the hairline first and then resecting the skin. I close the hair-bearing scalp with staples and two layers of Monocryl, including a final intracuticular layer behind the ear. When closing behind the ear, it is important to include the deep fascia in the retroauricular sulcus within the closure; this will prevent outward migration of the retroauricular scar. Dressings and postoperative management are the same as described earlier.

Results

This middle-aged woman, seen preoperatively and 5 years postoperatively, underwent an endoscopic brow lift, upper and lower lid blepharoplasty, face and neck lift with platysma plication, and CO₂ laser resurfacing of the forehead and perioral area. The split-face view demonstrates that brow position has been maintained and platysma bands have been eliminated.

This middle-aged patient underwent a face and neck lift, with upper and lower lid blepharoplasty. No subcutaneous fat was removed from her neck. Her improved contour is the result of subplatysmal procedures, including digastric and submandibular gland excision.

This woman had a lower lid blepharoplasty, face and neck lift, including a submental incision, subplatysmal fat removal, and platysma plication. Her postoperative result demonstrates smooth recontouring of the neck.

This patient in her sixties is shown 3 years after a full-scar face lift, a neck lift with no fat removal, a temporal brow lift, an upper lid blepharoplasty, a lower lid blepharoplasty including fat preservation, orbicularis redraping, and canthopexy. An oblique view of her in her twenties is included. The only flaws in an otherwise good result at 3 years are the wrinkles around her lateral brow and central neck. This is related more to skin quality than to the effectiveness of her face and neck lift. A resurfacing procedure at this stage would be beneficial.

This middle-aged patient underwent a face and neck lift, including subplatysmal fat removal and platysma plication. No subcutaneous fat was removed to maintain a 5 mm layer of fat over the platysma. The improved neck contour is the result of subplatysmal procedures and platysma plication.

Problems and Complications

The most common error I see in neck recontouring is overoperating in the superficial plane to mask or improve intermediate or deep plane problems. The tendency is to overdo the removal of subcutaneous fat, rather than dealing with problems related to interplatysmal or subplatysmal fat, the digastric muscle, and submandibular gland. Reluctance to deal with the deeper layers in the neck leads to suboptimal contouring. The excessive removal of subcutaneous fat leads to adherence of the denuded dermis directly onto the platysma muscle, contraction bands, and unusual skin tethering that is most obvious on movements involving the platysma. Although correction of untreated subplatysmal contour problems is relatively straightforward, improvement of skin-platysma adhesions is very difficult.

Preoperatively, this patient demonstrated neck irregularities, reflecting overzealous subcutaneous fat removal in a previous surgery rather than a subplatysmal procedure to recontour the neck. The problem was further compounded by skin dyschromias resulting from CO₂ laser resurfacing. Excision of digastric muscles and submandibular glands improved her contour; however, the problem of adhesions of skin directly to the platysma is extremely difficult to overcome.

I have found that full mobilization of the skin off the platysma with secondary re-draping offers some improvement. Autologous fat, dermis grafts, and acellular dermal matrix are suitable options for improvement of such problems.

Another common error with neck lifts is related to vectors. The preferred vectors include an upward vector in the face and a diagonal posterior vector. Excessive posterior traction on the neck without adequate vectors of elevation anteriorly along the jawline will lead to a banding or a “hammock effect” whereby the lower and posterior neck are effectively tightened, but laxity remains in the submental area, jowls, and neckline.

This patient, who had undergone two previous face lifts, demonstrates the inappropriate vectors and planes of intervention employed during her previous face lifts. She is shown 1 and 2 years after a tertiary face and neck lift, with redirection of SMAS and skin vectors and subplatysmal recontouring.

Secondary problem areas include the following:

- Skin
- Fat
- Platysma
- Digastric muscles
- Submandibular glands
- Inappropriate vectors

Skin problems following neck lifts are usually related to failure of adequate redraping as a consequence of insufficient undermining or poor skin quality. Most often, however, the cause is undercorrection or failure to correct the jowls, jawline, and the neck-face interface. Correction requires a face lift with appropriate management of the facial skin.

Fat problems are related to overexcision or underexcision. Overexcision is most often performed in the subcutaneous plane; this can be avoided through the use of smaller cannulas, turning the hole away from the skin, limiting the passes in each tunnel, and striving to leave a uniform 3 to 5 mm thickness of fat deep to the skin. Underremoval of fat is most often seen deep to the platysma and adjacent to the submental incision itself. These can be avoided through proper planning and appropriate management of each plane or layer of the neck.

The most frequently encountered problem with the platysma is the persistence of platysma bands. These occur when the bands are not dealt with primarily or when the plication sutures fail. Solutions include reoperation to plicate or resect as indicated, or temporary treatment with *botulinum* toxin injections. Alternative approaches such as transcutaneous division of platysma bands, as advocated by Gonzalez, and stairstep division of the platysma, as described by Saylan, are appropriate options.

A persistent bulge following neck contouring in the submental area most often is the anterior belly of the digastric muscle, which may have been unmasked when subcutaneous fat was removed. Correction is relatively straightforward, entailing digastric excision through a submental incision.

Bulging in the submental triangle results from an enlarged submandibular gland. Most often this was present preoperatively and was not dealt with or was unmasked by subcutaneous defatting. Correction entails a submental approach and partial excision.

Appropriate vectors in the neck include an upward vector in the submental area where the skin redrapes, an upward vector along the jawline, and a diagonally posterior vector behind the ear. For an optimal result, a balance must be struck among these vectors. Excessive traction in any one of these vectors without appropriate countertraction in the others will result in banding or a hammock effect. Correction includes reoperation and remobilization with more balanced traction.

Concluding Thoughts

The neck does not always have to be opened in order to be recontoured and rejuvenated, nor is it necessary to operate deep to the platysma in every patient. A full pre-operative assessment of the three planes, together with intraoperative evaluation, will indicate the procedure or procedures that will most effectively recontour the neck.

Clinical Caveats

The surgeon should avoid overoperating in the subcutaneous plane to overcome deeper problems.

For optimal results, the deeper planes must be approached and modified directly.

For liposuction, cannulas of 3 mm or smaller in diameter should be used.

Patients must be evaluated for platysma bands and subplatysmal fat before liposuction.

Liposuction may unmask preexisting platysma bands.

Liposuction should be avoided in patients who have fat superficial and deep to the platysma, because results will likely be suboptimal.

The number of liposuction passes should be limited to one or two in each tunnel.

The cannula hole should be turned away from the dermis.

Undermining widely is recommended to achieve adequate skin redraping.

Stretched, inelastic skin will not redrape and must be resected.

Recontouring the neck without addressing the lower third of the face will yield suboptimal results.

At least 3 to 5 mm of subcutaneous fat should be left on the skin flap.

Subplatysmal fat should be removed rather than overresection of subcutaneous fat.

The need for digastric or submandibular gland excision should be evaluated intraoperatively.

Submandibular gland excision is performed within the capsule of the gland.

Submandibular gland excision is approached in a piecemeal fashion.

The surgeon must maintain harmony between the lower third of the face and the jawline.

Resurfacing (20% TCA) should be considered to improve skin quality in the neck.

Annotated Bibliography

Connell BF, Shamoun JM. The significance of digastric muscle contouring for rejuvenating the submental area of the face. *Plast Reconstr Surg* 99:1586-1590, 1997.

The authors present the technique of partial resection (tangential excision) of the anterior belly of the digastric muscle. They also discuss the benefits of this procedure; they have found that it results in a well-contoured submental area, prevents residual fullness, is easy to perform, and averts the need for secondary neck-contouring procedures.

Ellenbogen R, Karlin JV. Visual criteria for success in restoring the youthful neck. *Plast Reconstr Surg* 66:826-837, 1980.

The authors suggest visual criteria for achieving and assessing success in platysma cervical lift. They think it is now possible to satisfy these criteria in most patients, even those with a low-lying hyoid. They also discuss techniques for restoring a youthful neck.

Feldman JJ. Corset platysmaplasty. *Plast Reconstr Surg* 85:333-343, 1990.

Contemporary surgery to rejuvenate the aging neck commonly includes some type of platysma modification. Corset platysmaplasty was developed to avoid postoperative imperfections. The author discusses the rationale and surgical technique for this procedure. A number of case examples are also presented.

Fuente del Campo A. Midline platysma muscular overlap for neck restoration. *Plast Reconstr Surg* 102:1710-1714; discussion 1715, 1998.

The author describes a variation of platysmaplasty, consisting of the overlapping (double-breasted fashion) of the platysma muscles in the midline, solely through a submental approach. This variation allows excellent platysmal suspension and neck recontouring, eliminating the need for posterior traction of the platysma muscle and in many cases avoiding the need for cervical incisions.

Guerrerosantos J. Neck lift. Simplified surgical techniques, refinements, and clinical classification. *Clin Plast Surg* 10:379-404, 1983.

The author describes his classification of the aging neck and his approach for rejuvenation of the neck. This article includes the original description of suspension sutures designed to improve on the jaw line and neck jaw angle.

Nahai F. Reconsidering neck suspension sutures. *Aesthet Surg J* 24:365-367, 2004.

In this article I note that in my experience the suspension sutures only temporarily improve and mask problems that lie deep to the platysma. The suspension sutures are designed to tighten the platysma and thus temporarily correct the deep problems. I have found that a direct approach to the fat digastric muscle and submandibular gland deep to the platysma provides longer lasting results. For this reason, I tend to limit the use of suspension sutures in my practice, and I prefer to approach these deeper tissues directly.

CHAPTER 49

Reoperative Rhytidectomy

JAMES C. GROTTING, WILLIAM J. VINYARD

Plastic surgeons today are seeing more and more patients returning to the practice, or presenting for the first time, with requests for facial rejuvenation after previous facial procedures. Primary face-lift patients' concerns are more generalized; the concerns of reoperative aesthetic patients vary but tend to be very specific. A secondary face-lift patient will often return and have common complaints such as "My creases (nasolabial folds) are back," "My neck is loose again," and "My kids ask me what I'm mad about when I'm not mad at all." Reoperative aesthetic patients are unique in that they already know what they're getting into. They wouldn't have returned to the surgeon if they were not prepared to have a correction. Generally, they will not be dissuaded by fear of pain, fear of anesthesia, or financial issues.

Every facial rejuvenation patient asks, "How long will my face lift last, Doctor?" Although it isn't possible to answer a query like that with precise accuracy, all plastic surgeons know that a face lift does not last forever. Patients must understand that surgery will turn the clock back for them, but the inexorable march of time will catch up with them once again. Patients will always look better than if they had not undergone the operation, although continued aging still occurs. Having a face lift is a very big decision for most patients. Yet having a second or third procedure is becoming much more common.

Educating patients about the possible need to "shore things up" at a future time helps to keep patients within a practice and helps grow one's experience with secondary procedures. If the patient's tissues have lost all elasticity and the subcutaneous fatty layer is full, the chances of requiring an early secondary correction are high.

There are generally five categories of patients who require reoperation. The first category is patients with complications following primary face-lifting. The second is those seeking adjunctive procedures to improve or enhance the previous results. These adjunctive procedures may not require traditional lifting procedures: the patient may only require less-invasive procedures to rejuvenate the face. The third category consists of individuals requesting reoperation for continued facial aging. In this group of patients, only a "tuck-up" procedure may be required. The fourth category is patients for whom the surgeon has previously planned a staged approach. There are two subsets to this: the first group consists of younger patients who require only minimal procedures, such as lipocontouring of the jowls or submental areas, and who subsequently undergo more traditional lifting procedures as they age. The other group comprises some of the most difficult patients to provide satisfactory results for in

one procedure. These patients tend to be older, with doughy skin, fatty facial tissue, and severe neck laxity that extends below the thyroid cartilage and into the sternal notch. They usually require early postoperative tightening procedures in the neck, even as early as 1 year. We find it best to counsel these patients preoperatively about their risk of early recurrence. The fifth category includes those who have not had any complications but are dissatisfied with the results they obtained from their primary facial rejuvenation procedure.

How is reoperative facial surgery different? Often there are asymmetries created by the previous operation that need to be addressed. The anatomy is different; the facial nerve can be in an unexpected place. This is especially true in a thin patient who has had multiple previous procedures. It is very easy to get into the wrong plane and damage the facial nerve; scar tissue and fibrotic adhesions create this altered anatomy. In addition, changes in the blood supply may dictate a new approach. In one way, the previously undermined skin flap can be considered a delayed flap, which is safe to reelevate, but in other situations it can be quite tenuous, especially in a patient who smokes.

In this chapter we will discuss the various reasons that patients request reoperative facial rejuvenation, the diagnosis and management of complications seen in primary rhytidectomy, aesthetic evaluation for reoperative facial rejuvenation, the anatomic differences that must be considered in secondary rhytidectomy, secondary face-lift procedure options, the prevention and correction of the “overoperated” look, and how to maintain the results of facial rejuvenation.

Reasons for Reoperative Rhytidectomy

Continued Signs of Aging

The inevitable signs of aging can be mitigated, but not halted. A patient may have previously been happy with the results of a primary rhytidectomy, but as the years pass, facial aging continues. The patient’s genetics and sun exposure influence the aging process. As we discuss later in this chapter, the appearance of the face as it ages is different in patients who have already had facial rejuvenation surgery. Therefore the approach to correcting facial aging is different in primary versus secondary rhytidectomy patients.

This 58-year-old woman had undergone a subperiosteal face lift and an open brow lift 14 years earlier. She felt that she had lost the rejuvenating glow of her primary face lift. Patients such as this want to maintain a certain look and are excellent candidates for secondary face-lifting. She is shown 1 year after undergoing a secondary face lift with an extended SMAS dissection and endoscopic brow lift.

Continued aging is the primary reason for secondary (or tertiary, and beyond) face-lift procedures. It is helpful if the surgeon knows exactly what was done in the initial procedure. In this case, the patient's lift had been performed in the subperiosteal plane, so in the secondary face lift we felt that a formal SMAS elevation would give the desired result while remaining in a plane free of previous scar.

Adjuvant Procedures to Enhance Previous Results

A patient's previous rhytidectomy may not have included treatment of midface descent, which has influenced his or her decision for a secondary rhytidectomy. Patients may want to add skin treatments with facial laser resurfacing, facial shaping with lipocontouring and/or lipofilling with autologous facial fat injections, or periocular and/or forehead rejuvenation to enhance the previous results. The neck may have been liposuctioned in the previous surgery, but skin tightening or platysma tightening might not have been performed.

Failure to adequately contour the jowl fat in the initial procedure may lead to the need for secondary lipocontouring and reelevation of the SMAS.

Planned Staged Intervention

As aesthetic procedures become more popular, patients are beginning to have facial rejuvenation procedures earlier in life. Many are starting with less-invasive procedures such as neurotoxin injections for improvement of dynamic rhytids, soft tissue fillers for static rhytids, and facial skin laser resurfacing for fine rhytids. At this early stage in the facial aging process, less-aggressive surgical procedures are required to satisfy their expectations, such as facial lipocontouring and/or lipofilling. However, these patients are counseled about the continued aging process and will likely request additional procedures years later.

This patient is a good example of a staged procedure over the course of 15 years. At age 36, she requested improvement of her jowls and submental regions. She was pleased with the results she obtained from suction-assisted liposuction (SAL) of the jowls and submental regions.

Six years later, the patient returned at age 42 and requested surgical correction of her neck and cheeks. She is shown 2 years after undergoing a rhytidectomy. As can be seen, the excess fat in her jowls and submental area were greatly improved with lipocontouring alone. However, as she continued to age, the deeper tissues began to descend, and the rhytidectomy allowed repositioning of the deeper structures and better definition of the jawline.

A planned, staged procedure should also be anticipated in patients who are typically difficult to achieve excellent results in one stage or in those with tissues that are prone to early recurrence of laxity. These patients can be identified by the poor quality of their skin and/or the heaviness of their tissues and should be counseled regarding the expected staged procedure so that the results that both the surgeon and patient anticipate can be achieved.

This 66-year-old woman had considerable loss of skin elasticity, with very loose tissues in the neck and a rounded facial appearance. This type of patient is a likely candidate for an early secondary correction, even as early as 1 year after the primary procedure, because of the probable recurrence of jowling and tissue laxity. Patients must be informed of this in advance to avoid dissatisfaction and unrealistic expectations. She is shown 4 months after undergoing an extended SMAS rhytidectomy.

The patient developed a postoperative neck hematoma. Although the hematoma was drained, she developed a fibrous mass in the central aspect of her neck that failed steroid injection therapy. She subsequently underwent direct excision of the mass 7 months after the initial procedure.

The patient returned 1 year after her primary rhytidectomy with persistent fullness in the jowls and requested surgical correction. She underwent SAL of the jowls and was pleased with the early results.

One year later, she began to develop early descent of the malar fat pad, prominent nasolabial and labiomental folds, and early signs of neck laxity.

4 months after primary extended SMAS rhytidectomy 1 year later: following SAL of jowls 18 months later: 6 months after secondary rhytidectomy

Six months after her secondary rhytidectomy, the patient was again pleased with the results; the recurrent jowling and tissue laxity have been significantly improved.

Dissatisfaction With Previous Results

Even if they have not had any surgical complications, some patients are still dissatisfied with the results from their previous rhytidectomy. It is very important for the reoperative surgeon to spend adequate time with these patients to clearly understand what their expectations are and to discuss with them in detail exactly what results can realistically be achieved. These patients may or may not have discussed their dissatisfaction with the results with their previous surgeon when they seek correction. It is important in this situation to obtain the patient record from their previous surgeon.

Early Complications

The face-lift operation, like any other aesthetic procedure, presents risk for early complications, as shown in the box.

Early Complications of Rhytidectomy

- Hematoma
- Infection
- Skin slough
- Nerve injury (sensory and motor)
- Dysphagia
- Emotional issues

Hematoma after a face lift is a significant source of morbidity. Various authors report the incidence among all patients at 1% to 12.9%. The risk factors for hematoma include hypertension, especially when it is uncontrolled preoperatively; male sex; bleeding disorders; and the use of various medications that interfere with coagulation. Clearly, prevention is paramount in reducing the incidence of postoperative hematoma. Blood pressure control pays the highest dividends in this effort. The incidence of hematoma among patients undergoing facial rejuvenation with local anesthesia and sedation may be a bit lower than for those who are given a general anesthetic. However, with either group it is crucial that blood pressure be normalized before the start of the procedure. If the patient's blood pressure remains greater than 180 systolic or 90 diastolic after initial sedation, we do not proceed until the blood pressure is diminished. Persistent elevation is an indication for referral and workup by the patient's primary physician. Clonidine has been recommended as a useful agent for preoperative control of blood pressure at doses of 0.1 to 0.2 mg orally the morning of surgery.

Men have a higher incidence than women of bleeding during face-lift procedures and more frequently develop postoperative hematomas (between 3.97% and 12.9% of cases). This phenomenon is probably caused by the presence in men's faces of more sebaceous glands and hair follicles, each of which is surrounded by a more extensive capillary network. As a result, the vascularity of male skin is increased, leading to greater potential for blood vessel disruption. Because of this phenomenon, more-limited undermining in men as well as a conservative closed approach to the neck can decrease the surface area at risk for postoperative bleeding. The use of fibrin glue has also shown some benefits for rhytidectomy.

We ask our anesthetists to avoid spikes in blood pressure as the patient emerges from general anesthesia, because this is the time of great risk for the development of a hematoma. Drains are useful as a monitoring mechanism for the amount of bleeding, but it is well accepted that they do not prevent hematoma. Head elevation, cool compresses, pain control, and continued sedation are all useful for maintaining blood pressure at an acceptable level.

Management of Hematomas

Hematomas that develop after a face-lift procedure can fall into two categories: small ones that can be drained at the bedside without returning the patient to the operating room, and large ones in which the cheek and/or neck must be reopened and explored to control the bleeding source.

Bedside Management of Hematomas

The key to successful management of a hematoma is early detection. When detected early, it is more likely that the hematoma can be managed without a return to the operating room. Bedside management is accomplished by removal of enough sutures or staples to be able to remove clots and fresh blood. Preparation for this procedure should include some oral pain medication or sedation if the patient is overly anxious. Blood pressure must be under good control. Thorazine and nitropaste are useful agents for decreasing blood pressure by vasodilation. Towels or "chucks" are spread beneath the patient's head, and the area is prepared with a solution such as povidone-iodine (Betadine) solution. A Yankauer suction tip or red Robinson catheter is helpful for evacuating all the clots; the surgeon can then assess ongoing bleeding. The area is irrigated profusely with saline solution until the return is clear. Then a solution of 20 to 30 ml of 0.25% lidocaine with 1:200,000 epinephrine is injected under the flap. Compression is held for 5 to 10 minutes, and a supportive circumferential dressing is applied.

Operative Treatment of Hematomas

If the hematoma is large and seems to involve both cheeks and the neck, a return to the operating room is indicated. Other factors that should influence the surgeon toward a return to the operating room are these:

- An uncooperative patient
- An overly anxious patient
- A large, delayed hematoma
- Labile blood pressure
- Bilateral hematomas
- A compromised airway

If the patient is having difficulty breathing, immediate removal of sutures and decompression are essential. Since intubation and airway control in the presence of a large hematoma can be exceedingly difficult, we prefer to initially get control of the situation with the patient under local anesthesia with a little sedation. Often very little is needed, because the tissues are frequently still numb from the initial procedure, and antianxiety and pain medications may already have been given. The surgeon must try to locate the primary source of fresh bleeding and pack that area while evacuating the remainder. With large hematomas, we usually remove the majority of the sutures to make absolutely certain that all sources of bleeding have been controlled, because the worst scenario is to think one has control of the bleeding source, only to find that the hematoma has recurred after the patient has left the operating room. Profuse irrigation with saline solution and dilute hydrogen peroxide will usually reveal the bleeding source. Of course, the surgeon can feel most confident when a single “pumper” is found. When multiple bleeding vessels are encountered, we prefer to keep the patient in the operating room under observation a bit longer until we are certain no further bleeding is going to occur. Drains should always be replaced and their proper function confirmed.

Four hours after undergoing a face lift, an endoscopic brow lift, and an upper and lower blepharoplasty, this 59-year-old woman developed an obvious hematoma involving both cheek pockets and the neck. Exploration revealed two arterial bleeding points in the neck that were controlled. All regions were washed out and the skin was reclosed.

The patient is seen 4 months postoperatively with near-complete resolution of the sequelae of this complication.

The consequences can be devastating if a large hematoma goes untreated. This 48-year-old woman was seen in consultation after having undergone a primary rhytidectomy in another state. Postoperatively she developed bilateral hematomas that were treated conservatively. She developed extensive preauricular and cheek scarring for which she underwent a “pickle-fork” procedure 5 weeks later. The patient presented to our practice 7 weeks after her primary rhytidectomy requesting correction of the deformity. She was depressed and was unable to resume her normal activities. The mainstay of treatment of any patient with significant deformity as a result of complications is to not reoperate too soon. In this situation we attempted conservative nonsurgical treatments, including ultrasound and endermologie, while waiting for the tissues to soften. Of key importance is avoidance of additional traumatic injury to the area by manipulation or injections. After 1 year we felt that the tissues and the patient were ready to undergo definitive correction. The plan was to release the scar tissue between the dermis and the SMAS and provide a pad of soft tissue between these layers. Because the patient also requested an abdominoplasty, we developed a plan to harvest dermal fat grafts from her pannus for use in the cheeks.

The dermal fat grafts were spread out and sutured under tension at the periphery of the released pocket. In addition, autologous fat injection was performed in the bilateral nasolabial folds. Very little facial skin was removed during this procedure, which is common in secondary face-lifting.

The patient is seen 3 years after the revisionary facial procedure. Although the lateral cheek rhytids have not been completely eliminated, they are greatly improved, the patient's depression has resolved, and she has resumed her normal activities.

Skin Slough

Skin sloughs usually occur as a result of closure under excessive tension. Blood under the flap, tight dressings, flexed neck positioning, smoking, and diabetes are all contributing factors. If impending tissue necrosis is diagnosed in the early postoperative period by flap cyanosis or lack of capillary refill, sutures should be immediately removed and the skin allowed to retract. As in the case of a released nipple-areola complex, the open wound can be covered with Xeroform and a light dressing for 5 to 7 days, at which time one is often able to reclose the wound with salvage of the skin flap. If hyperbaric oxygen therapy is available, treatments once or twice daily for 5 days can be helpful in salvaging underperfused skin flaps.

If the skin is clearly demarcating, usually conservative treatment is indicated. The surgeon should make certain that the patient is not continuing to smoke if he or she is a smoker. These patients will require repeated reassurance, because this complication may seriously affect their ability to return to work or other social activities. On the other hand, little wound care is necessary in the eschar phase. When spontaneous separation begins to occur, we debride any nonviable tissue and begin dressing changes. Allowing the wound to contract and heal spontaneously usually gives a result that is a better color and texture match than a skin graft would. Obviously, if flap advancement and reclosure is a possibility, this is the best option. However, usually there is too much tension to accomplish this.

Infection

Fortunately, infections following face lifts are rare, but they can have devastating consequences. Prevention is the key. We have all our patients wash their faces themselves at least three times with an antibacterial soap on the morning of surgery. It is difficult to maintain a strict sterile field with facial rejuvenation surgery because of the presence of hair and the oral and nasal cavities within the field, as well as the endotracheal tube or airways and oxygen. Nevertheless, every attempt must be made to avoid contamination, especially when the procedure is prolonged. We have found that soaking braided sutures in Betadine before use has decreased small suture infections, especially in the region of the platysma plication. Also, before closure of the cheek dissection, we meticulously irrigate all open areas with dilute Betadine to wash out any debris, particularly loose fat globules.

Infections may arise in undrained hematomas or seromas; these are often seen as collections in dependent portions of the undermined area. An overlying erythema is usually the first sign, but there may be little or no associated pain or fever. Drainage is of paramount importance, even more crucial than appropriate antibiotic selection; however, cultures should be obtained to guide antibiotic selection. If the combination of drainage and antibiotic agents fails to rapidly resolve the problem, operative exploration should be considered to rule out an infected foreign body. Cotton used to plug the external auditory meatus has been known to drop into the wound and should be accounted for in the sponge and needle counts. In severe infections of the face, thorough irrigation, debridement of any nonviable tissue, and wide drainage is generally effective, in addition to administration of an appropriate antibiotic. Hospitalization and intravenous antibiotic therapy are rarely needed, but anything less than rapid resolution of the infection should be treated in this manner.

Parotid Fistula

Parotid injury has become a more common event with face-lift techniques that involve dissection in the sub-SMAS plane. Unfortunately, it is even more likely when the SMAS has been previously elevated, as in some secondary face lifts. With any secondary facial procedure the parotid is at greater risk of injury because of altered anatomy and scarring. The gland is at highest risk over its superficial lobe, just at the mandibular angle. The superficial fascia can usually be separated from the parotid fascia unless the plane has been previously obliterated surgically. Actually, raising both the superficial fascia and the parotid fascia in continuity is sometimes advantageous when the superficial fascia is thin, because this adds strength for the deep tissue fixation. However, one is dissecting right on top of the glandular lobules of the parotid, which can look very similar to the sub-SMAS fat and is therefore susceptible to injury. This is how most parotid injuries occur. The duct is rarely injured but can be obstructed if the gland is torqued by suture fixation.

The key to management is to recognize the injury to the parotid at the moment it occurs so that the plane of dissection is immediately corrected. The injured parotid is simply coagulated with the electrocautery or rarely, oversewn with fine sutures if the injury appears to enter the terminal ductules. The area is drained and compression applied for 48 hours. If there is obvious saliva appearing in the drain, the drain should remain in place until the output is minimal. Generally, these fistulas are self-limited as long as the duct is not obstructed. Sialography or duct endoscopy had been reported to be helpful in reopening an obstructed duct. Injuries late in the postoperative period are diagnosed by a swelling and fluid collection over the parotid that on aspiration yields a high amylase titer. Generally, the patient is afebrile. The swelling often increases with eating. It is managed by inserting a closed suction drain, adding a pressure dressing, and administering antibiotic agents. Atropine and glycopyrrolate have been reported to be helpful for their antisialagogue effects.

Nerve Injury

Any branch of the facial nerve can be injured during a face lift. With the anatomy altered from primary surgery, deeper dissections beneath the SMAS during secondary face lifts risk injury to the facial nerve. The frontal branch of the facial nerve is the most commonly injured branch, followed by the marginal mandibular and the buccal branches. Although severed branches do occur, the more typical injury results from traction or thermal injury from the use of cautery in close proximity. The vast majority of nerves which are still in continuity recover in time although this can take up to a year or more. Most recover within 2 weeks to 3 months.

When frontal branch weakness is noted postoperatively and persists beyond 1 month, we favor the use of *botulinum* toxin to weaken the normal side of the face if the patient will accept it while the injured side recovers. Often, as the *botulinum* toxin wears off, the nerve has recovered on the injured side and symmetrical movement is reestablished.

If the nerve has not recovered by 1 year after surgery, a more permanent solution is to perform either a direct or an endoscopic brow lift on the affected side, as well as on the normal side, if indicated. A similar strategy can be used for the marginal mandibular branch with weakening of the depressor anguli oris on the normal side with *botulinum* toxin. Resection of this muscle has been reported for perioral rejuvenation and could be considered if the smile remains asymmetrical beyond 1 year. Injuries to the great auricular nerve are usually managed conservatively; often sensation will return spontaneously.

Dysphagia

Dysphagia is attributable to platysmal tightening, which is a dramatic change for patients who are accustomed to a loose neck. Diazepam is effective for symptomatic treatment early on, and no surgical intervention is ever indicated, because the muscle always relaxes with time.

Emotional Issues

Recovery from a face lift is an emotional rollercoaster for some patients. The effects of anesthesia, steroids, and other medications as well as fear of their eventual appearance can take a serious toll on the emotional well-being of face-lift patients. Pre-operative education can help prepare them for “the blues” that frequently accompany the recovery process. Having a relationship with a clinical psychologist in your community can pay great dividends if intervention seems to be necessary and you need to refer the patient. For most individuals, reassurance is all that is necessary until the swelling and associated distortion has resolved. A recent patient satisfaction long-term follow-up study showed that the overwhelming majority described their improvement in facial appearance as “very good” or “beyond expectations.”

Aesthetic Evaluation for Reoperative Rhytidectomy

With better understanding of the aging process, we now know that repeated pulling of the skin, especially in a disadvantageous direction, will not restore a youthful appearance, but rather yield an appearance that belies repeated surgery and may be exceedingly difficult to correct. The lateral sweep of the lifted lateral cheek and jowl but uncorrected midface is a classic example of this. Therefore patient evaluation must begin by careful analysis of which features are yielding an aged appearance.

Although the aesthetic evaluation for a secondary rhytidectomy is similar to that of a primary rhytidectomy, there are certain physical examination characteristics that may differ. There is on average 8 to 12 years between the time of the primary rhytidectomy and the secondary rhytidectomy. During that time, the patient's skin quality and texture deteriorates from further actinic damage. In addition, some areas of the face retain their tightened support, whereas other areas, such as the midface, continue to descend, creating an unnaturally aged appearance. Other unnatural appearances created by a previous rhytidectomy include distortion of the hairline and sideburns, malposition of the earlobe, loss of tragal definition, facial asymmetries, cross-cheek depressions, and visible scars. It is important to recognize these changes so that an appropriate and accurate treatment plan can be formulated.

Factors to Be Considered in Secondary Facial Rejuvenation

Quality and texture of skin	Visibility and quality of previous scars
Degree of skin relaxation	Perioral lines, lip thickness and length
Degree of fat atrophy with residual hollowing	Platysmal banding and laxity
Facial asymmetries	Submandibular gland prominence
Depth of nasolabial, labiomental, and nasojugal creasing	Chin shape and ptosis
Ear and earlobe malposition, ptosis, and deformities	Contour deformities of the neck resulting from excess fat in neck or jowls
Tragal definition and position	Malar flattening
Hairline shifts or hair loss	Digastric muscle prominence
	Dentition

It is a mistake to immediately conclude that what every patient must have is your definitive face lift, as if whoever did it the first time might be lacking your skill. Many patients may have come to you because they have heard that you are not a surgeon who immediately wants to do another face lift on everyone. You now have multiple approaches available, so the first rule is to *listen to your patient!* Then ask, “What is it about your face that is beginning to bother you?” and “Were these features improved after your first face lift?” Starting with questions like these will assist you to tailor valuable consultation time toward the patient’s primary concerns rather than discussing all sorts of items that the patient will simply not consider. Nevertheless, the consultation is also an opportunity to help educate the patient about procedures or treatments that will give lasting improvement versus treatment options that he or she may have heard about but for which the patient is not a candidate. *Botulinum* toxin and fillers are, quite obviously, not going to produce a face-lift-like result, but some patients are confused about issues such as these.

In recent years, much more attention has been paid to the midface as well as to volumetric shaping of the face. These are issues that might not have been addressed during the patient’s initial face lift. Of course, if the patient returns to the surgeon who performed the original procedure, access to the original records will be at hand. If the original surgery was done by someone else, it may not be possible to determine the exact technique and what was done the first time around. If the assessment reveals an aged midface appearance, this will need to be addressed during surgery. Also, the addition of fillers, including autologous fat grafting for volumetric replacement, is more commonly done today. Therefore it is likely that the patient has not benefitted from some of the newer technologic innovations that plastic surgeons have available to them.

Often the quality of the skin has either further deteriorated or has never been treated in a secondary patient. This may be the primary source of concern for the patient, and improvement is more a matter of resurfacing, filling, or skin care.

Anatomic Differences in Reoperative Rhytidectomy

Skin and Scars

During the interval between the primary rhytidectomy and the planned secondary rhytidectomy, the patient's skin continues to age and thin. There is ongoing loss of collagen in the dermal layer, which causes increased skin laxity and a decreased ability to maintain support with tension. As mentioned earlier, the degree to which the tissues lose support depends on the anatomic area. Although the preauricular area maintains a high degree of support, evidenced by the lack of excess skin in this area removed in secondary rhytidectomy, the preauricular scars can become noticeable with small amounts of migration.

The postauricular scars are also vulnerable to this migration and visibility. The surgeon should make every effort in either a primary or a secondary rhytidectomy to place the scars in areas that are least noticeable.

The patient's scars from previous procedures are an important consideration when planning reoperative surgery. The character of the scars should be noted. Although rare, scars may have developed into hypertrophic or keloid scars. These scars may be improved with a secondary procedure, but the patient must be aware that they may

recur or even worsen. The location of the scars limits the surgeon's ability to place the scars of a secondary procedure in an inconspicuous location. The surgeon should try to place the final scar in an ideal location but should not commit to the final location until after the skin flap has been elevated and the amount of excess skin determined.

Hair Line

A previous temporal incision may have decreased or completely eliminated the patient's sideburns. If the distance between the lateral canthus and anterior portion of the patient's sideburn is long, an anterior hairline incision should be considered to prevent the loss of the patient's sideburn. The incision is usually inconspicuous and is much more attractive than the loss of the sideburn. We try to stay below the sideburn whenever possible and extend the incision as required for adequate skin redraping in the lateral temporal region.

Subcutaneous Tissue

In secondary rhytidectomy patients, the amount of subcutaneous tissue under the previously undermined skin is atrophic. The previous elevation of the skin flap functions as a “delayed flap,” which provides a better blood supply to the skin. It is less likely to have skin blood supply issues unless the patient is a smoker. In such a case, it is important for the patient to quit smoking for at least 4 weeks before surgery and for 4 weeks after. Although the blood supply is of less concern in a secondary rhytidectomy, the previous elevation causes scar tissue to form, and in combination

with atrophic subcutaneous tissue, there is an inability to dissect distinct layers, as in this patient, who had undergone three previous rhytidectomy procedures. It is recommended to proceed with knife dissection until the planes are well established.

Previous SMAS Elevation

It is important to determine from the patient's medical documentation whether the SMAS was elevated in the previous rhytidectomy. If not, a secondary procedure provides a good opportunity to improve the midface with tension on the underlying structures. If the SMAS has been elevated previously, the scar tissue between the SMAS and the underlying parotid fascia is much more difficult to separate. The mobility of the SMAS should be assessed to determine whether plication alone will accomplish the improvement desired.

This is a patient who had previously undergone a primary rhytidectomy with an extended SMAS dissection. She had concerns for recurrent facial aging in the lower third of her face and underwent a secondary rhytidectomy. During the procedure the amount of correction needed to rejuvenate the lower third of the face could be achieved with SMAS plication alone. The markings before the plication can be seen.

Facial Nerve Risk With Reelevation of SMAS

When the SMAS has been elevated previously, the facial nerve is at a greater risk during dissection. In this situation, it is usually safer and easier to plicate the SMAS in the areas that produce the effect that is desired.

This patient developed a marginal mandibular neuropraxia after a primary rhytidectomy with SMAS elevation. Three years later, she returned with concerns for early recurrent neck laxity and prominent labiomental folds. Because of her prior nerve injury with SMAS elevation, we elected to use SMAS and platysmal plications for correction.

Surgical Options for Reoperative Rhytidectomy

Determining which procedure is best for a patient depends on many variables. A good understanding of what the patient's goals are will help to narrow the options. Once this is understood, determining what techniques were used in the previous surgery will help to establish the surgeon's risks and limitations.

Secondary Face Lift Options

- Isolated neck lift
- Threads/suspension suture technique
- “Tuck-up” procedure/mini-face lift
- SMAS procedures (complete, extended, or plication)
- Endoscopic approach to the midface
- Facial shaping and volume restoration with autologous fat injection
- Facial lipocontouring with liposuction

Preventing and Correcting the “Overoperated” Look

Know When to Say When

The overoperated look can occur from a single poorly performed procedure or from multiple procedures performed on the same person. If a surgeon has performed multiple facial aesthetic procedures on a patient, yet he or she is requesting improvements that will inevitably produce an unnatural overoperated look, the surgeon must use better judgment and decline to proceed. It is important to thoroughly explain why further surgical intervention could cause an unnatural and uncorrectable appearance, so the patient does not seek surgical correction elsewhere. Such a pursuit would inevitably lead to further patient dissatisfaction and could also damage the reputation of the surgeon and the practice.

The Lateral Sweep

In this patient with sun-damaged skin and facial wrinkling, the wrinkles run in a cephalad direction as the result of a previous face lift. This problem usually becomes more evident with animation and when the patient flexes the neck.

The term *lateral sweep* is given to the unnatural appearance of the cheeks after facial rejuvenation surgery when there is a distinct curve of the lower facial skin from the jawline toward the superior portion of the ear. The curved rhytids present an obvious overoperated look.

The lateral sweep is created because of skin tension differences between the pulling vectors of the lifted tissues. The greatest tension on the skin is superolateral toward the superior aspect of the ear, where the skin is anchored. The central portion of the face, the midface, is farthest from the skin anchoring and therefore has the least skin tension.

As the face ages, skin tension lessens and begins to descend. In an unoperated face, the tissues descend at equal rates, creating the normal stigmata of facial aging: an obvious lid-cheek junction, prominent nasolabial folds, marionette lines, downturned oral commissures, jowling, loss of an obvious jawline, and cervical laxity with the development of an obtuse cervicomenal angle. However, in a patient who has undergone facial rejuvenation surgery, the tissues descend at differing rates, because after the surgery, the skin and deeper tissues are under different tensions. As mentioned earlier, the tissue of the midface is the farthest from the point of fixation after a rhytidectomy and therefore has the least amount of tension. As the operated face ages, the areas of least tension, the midface, begin to descend earlier. As the midface descends and the inferior and lateral tissues retain their tension longer, the lateral sweep is created.

Deeper tissue manipulation using the SMAS is used to try to minimize this occurrence by resuspending and tightening the tension on the midface tissue. However, the point of fixation for this tissue is not as durable as it is for the skin and therefore still ages earlier. The composite rhytidectomy described by Hamra involves repositioning of the orbicularis oculi muscle in an attempt to strengthen the support of the midface and to minimize the bunching that can occur in the periorbital area.

Tragal Distortion

Tragal distortion is a telltale sign of the overoperated face. It is caused by excessive skin tension at the tragus when the incision is brought behind the tragus to disguise the scar. This can be prevented by placing key sutures that will hold the majority of the skin tension at the superior extent of the incision near the anterior and posterior aspects of the ear. After these sutures have been placed, the excess skin can be judiciously excised near the tragus to prevent any skin tension at this point. In addition, we also remove some of the excess fascial tissue directly anterior to the tragus to create the natural depression that should be present and use a deep dermal suture (5-0 PDS) to hold this depression in place.

If a previous surgery has created anterior displacement of the tragus as a result of excessive skin tension, there are techniques to recreate the natural appearance. The base of the tragus can be incised and released using a No. 15 blade scalpel, and a 5-0 nylon suture can be placed between the concha and the tragus to hold it in position. This suture is removed in the clinic 3 weeks later.

Hairline Distortion

Secondary rhytidectomy procedures can cause hairline distortion, especially at the level of the sideburn. If the previous rhytidectomy incision extended into the temporal hair, then chances are the length of the patient's sideburn has been shortened. Although less skin is removed during a secondary rhytidectomy compared with a primary rhytidectomy, any additional loss of sideburn hair will look overoperated and unnatural. In this case, it is best to extend the incision just below and then cephalad anterior to the sideburn. This incision should be beveled at an angle of 30 to 45 degrees to the external skin surface to permit hair growth through and anterior to the scar. The resulting scar can be inconspicuous and does not risk causing hairline distortion. The area of skin between the previous scar and the new incision should have an adequate blood supply.

Pixie Ear and Earlobe Scar Migration

A *pixie ear* forms when there is too much skin tension at the base of the earlobe inset. This causes an elongation of the earlobe at the site of the inset that is unnatural and is an obvious overoperated look.

This can be prevented by redistributing the skin tension to the appropriate place with key sutures of 3-0 nylon at the superior extent of the anterior and posterior ear. Once these key sutures have been placed and the tension removed from the base of the ear, judicious skin excision can be performed. To further reduce the potential of developing a pixie ear, an area of excess skin at the base of the ear can be deepithelialized and sutured to the base of the concha. This is especially helpful during a short-scar face lift, where the postauricular incision stops at the base of the earlobe. In this case, there is no posterior-superior key suture to redistribute the skin tension. This suture will act to minimize the skin tension at the base of the earlobe inset.

Earlobe scar migration can also be a problem after primary rhytidectomy. Although most scars can be hidden by the patient's hair or make-up, this scar can be very upsetting to the patient. After the scar has had time to mature, this abnormality can easily be treated in the office under local anesthesia. The scar tissue can be deepithelialized and sutured to the caudal portion of the conchal cartilage to provide added support. The skin should be rotated posteriorly, as in this patient, to recreate the natural aesthetic of the earlobe-cheek junction.

Obvious Scars

Visible scars are an obvious sign of an operated look. Most patients would prefer to have the scars hidden from view. This can be accomplished with placing the anterior incisions in or near the hairline and within the natural facial creases adjacent to the anterior portion of the helix and earlobe and at the tragal margin. As the incision continues around the posterior aspect of the ear, the incision should continue in the posterior auricular crease. The incision should continue high before extending horizontally into the posterior hairline. With this incision, the well-healed scars will be very difficult to visualize. If the posterior horizontal incision is placed low, the scar is quite obvious and hinders the patient's ability to hide the scar when the hair is cut short or pulled back.

It may be possible to reposition these scars higher if the incisions were initially placed low or if tissue laxity has recurred and moved the incision lower. One should not commit to the final location of this scar until the entire skin flap has been reelevated and the excess amount of posterior skin is known.

Another rare complication of rhytidectomy is hypertrophic or keloid scar formation. This patient underwent primary rhytidectomy and revision of an anterior vertical midline chest keloid scar. She had other scars that had not developed keloid formation. She was counseled on the risks of obvious scar formation with her known history, but she elected to proceed with the operation. Postoperatively, we treated her with Kenalog-40 injections diluted with 1% lidocaine, with slight improvement.

Recognizing Body Dysmorphic Disorder

When discussing any reoperative aesthetic surgery, it is important to recognize patients with body dysmorphic disorder (BDD). There are three diagnostic criteria listed for the diagnosis:

1. A preoccupation with an imagined or slight defect in appearance
2. Marked distress or impairment in social, occupational, or other areas of functioning resulting from the appearance preoccupation
3. The preoccupation is not attributable to the presence of another psychiatric disorder

Patients with BDD may visit the plastic surgeon for correction of their presumed deformity. It is imperative that the surgeon know the signs of this disorder and refer these patients to the appropriate mental health specialists. It has been reported that patients with this disorder who have undergone corrective surgery have a high rate of dissatisfaction with the results and have even become physically violent. (See Chapters 1 and 8 for more detailed discussion of this disorder.)

How to Maintain Your Results

“How Long Will My Face Lift Last, Doctor?”

As mentioned earlier, most patients want to know the answer to this question in their initial consultation. Patients who have already undergone a primary rhytidectomy have a better understanding of what to expect. Although it is impossible to accurately predict the longevity of this procedure for any given patient because individual differences in current age, skin laxity, actinic damage, genetics, previous procedures, and many other factors, studies show that 10 years is a good estimate.

Over the years, we have learned that the final result and longevity are influenced by the types of procedures performed. Facial rejuvenation has evolved from simply a skin-excision procedure to skin excision with manipulation of deep structures to skin excision with manipulation of deep structures and the inclusion of adjuvant procedures, such as chemical peels, laser resurfacing, dermabrasion, muscle modulation with neurotoxin, and volume restoration with soft tissue fillers, implant augmentation, and/or autologous fat injections. With these various combinations, the procedures can be tailored to the individual's desires and goals to obtain the best results and to improve longevity.

Lipofilling/Lipocontouring

Even with the evolution of rhytidectomy from skin-only resection to skin resection combined with repositioning of deep tissue support, patients and their plastic surgeons longed for improvement in certain areas that were poorly corrected by rhytidectomy. The areas of most concern are in the supraorbital hollow, tear trough deformity, prominent nasolabial and labiomental folds, and the jowls. These areas are either not improved after rhytidectomy, or they develop early recurrence of the deformities.

As the face ages, facial fat begins to descend (creating prominent nasolabial folds, labiomental folds, and the lid-cheek junction), atrophy (creating the supraorbital hollow, temporal hollow, tear trough deformity, prominent zygomatic arches, and cheek depressions), and accumulate (creating the jowl). The results of these facial changes create shadows at these anatomic transitions like that created in a valley between two mountains. To minimize this shadowing, one would either need to fill the valley, decrease the size of the mountains, or a combination of both. As facial rejuvenation has evolved, we have learned that the face should be analyzed and treated as a three-dimensional structure and that we must correct not only the skin and deep tissue laxity but also the volumetric changes seen with aging.

With the improvements in technology, such as ultrasound-assisted liposuction (UAL), and techniques of autologous fat injection, we can now improve these facial areas that have been resistant to long-lasting facial rejuvenation. Liposuction (either SAL or UAL) can remove the fat in areas of excess (analogous to decreasing the size of the mountain); fat injection can add the fat needed in areas of deficiency (analogous to filling the valley). Despite the lack of quantitative evidence of fat survivability, clinical experience demonstrates its benefits. The combination of facial rejuvenation lifting techniques with autologous facial fat injection and facial liposuction has significantly advanced the field of facial rejuvenation by facilitating correction of the volumetric changes seen with aging.

We prefer the use of UAL to slowly and precisely remove jowl fat in patients with lipodystrophy in this area. After repositioning of the malar fat pad and SMAS in a rhytidectomy, we carefully harvest fat for lipofilling of the areas of facial fat atrophy. The donor site chosen depends on the patient's preference and on adequate adipose stores. We most commonly use the lower abdomen. This combination of repositioning the malar fat pad with deep tissue support and replacing lost fat and/or removal of excess fat has significantly improved the lasting results of facial rejuvenation. These techniques can be used in a secondary rhytidectomy to help improve contour irregularities caused by previous facial procedures.

Soft Tissue Fillers

Soft tissue fillers can also be employed as a nonsurgical temporary treatment of facial aging. Many products have been used for soft tissue filling, but hyaluronic acid products have some of the most widespread use. They differ based on the amount of cross-linking present and their particle size. In general, the larger the particle size and the more cross-linking present, the longer the results tend to last. The soft tissue fillers differ in the material that is injected and their longevity. They can be used for facial sculpting and are most frequently used for temporary improvement of prominent nasolabial and labiomental folds, lip augmentation, and tear trough deformities. (See Chapter 12 for a more detailed description of these products.)

Dermabrasion

With the use of a small hand-held electrically powered instrument and an abrasive substance, such as a wire brush or diamond fraise, the epidermis and a portion of the superficial dermis is removed. The dermal appendages allow reepithelialization to occur in approximately 7 days, thus improving the surface texture of the skin. This technique can be used to improve acne scars and deep, coarse rhytids in the perioral area. The pilosebaceous glands of the face should be present in the skin for reepithelialization to occur. This technique should not be used in areas with a paucity of pilosebaceous glands due to the risk of abnormal scar formation. (See Chapter 14 for a detailed description of this technique.)

Laser Resurfacing

Laser skin resurfacing can be performed at the same time as a rhytidectomy. However, deep tissue penetration should not be used over the undermined skin unless the fractional technique is used. We do not resurface the lateral cheeks, since this is the area most at risk for healing problems because of the decreased blood supply in this area of the skin flap. Deep perioral resurfacing will improve the vertical rhytids around the lips that are not corrected with a rhytidectomy. Deep periorbital resurfacing can be used to tighten loose skin around the eyes in patients who have previously undergone a blepharoplasty or in those with minimal excess skin. A micro-laser peel can be performed on the central portion of the face in conjunction with a rhytidectomy to remove up to 30 microns of epidermis; this will improve the patient's complexion and remove superficial pigmentation changes. The ProFractional laser technology improves skin tone through collagen remodeling. With this technique, microholes are made in the skin using the laser set at varying depths. As the skin remodels, collagen is laid down and tightens the skin.

Chemical Peels

A chemical peel can help to improve the actinic changes of the skin. However, this procedure should be performed after the patient has healed from the surgical procedure. The epidermis and varying degrees of dermis are removed through a chemically induced injury. A neocollagen-rich layer replaces the dermis and reepithelialization occurs. Different peels are available, including phenol peels, trichloroacetic acid (TCA) peels, and glycolic acid peels. The depth of the peel is determined by the type and concentration of the chemicals used. (See Chapter 15 for a more detailed description of the available chemical peels used.)

Neurotoxin

Botulinum toxin is produced by the bacterium *Clostridium botulinum* and causes muscle paralysis. The neurotoxin inhibits the release of acetylcholine at the presynaptic cholinergic neuromuscular end plates. It was originally used to treat strabismus in the 1970s but is currently used most frequently for improvement of dynamic facial rhytids.

Neurotoxin injections can be used to treat glabellar furrows (formed by the contraction of the corrugators supercilii and procerus muscles); horizontal forehead rhytids (formed by the contraction of the frontalis muscles); periocular crow's-feet rhytids (formed by the contraction of the orbicularis oculi muscles); marionette lines (accentuated by the contraction of the depressor anguli oris muscles); and vertical lip rhytids (created by the orbicularis oris muscles). In addition, with appropriate placement of the neurotoxin, the shape and position of the eyebrows can be changed to improve eyebrow aesthetics.

Skin Care

Maintaining good skin health will help to improve the appearance and longevity of the surgical results. There are many skin care products on the market today, but the first step in good skin care is to avoid sun exposure. The genetic factors that contribute to the aging of skin cannot be altered through behavioral changes, but the effects of sun exposure can. We recommend that all of our patients be consistent in their use of sunscreen products and sun exposure protection.

Patient Examples

This 60-year-old woman had undergone a primary rhytidectomy 4 years earlier and was concerned about recurrent neck laxity and skin excess. She is seen 2 years after an isolated neck lift.

This 47-year-old woman complained of continued facial aging and prominent scars following an initial face lift at age 36 and a mini-face lift at age 41. The presideburn scars were visible, as was descent of the malar fat pad and minor jowling. We performed a tertiary face lift that included an extended SMAS technique to anchor the malar fat pad to the malar periosteum. Her results are seen at 1 year.

This 60-year-old woman had undergone an endoscopic brow lift, mini-face lift, and lower lid blepharoplasty 4 years earlier. She was displeased with the appearance of her eyebrows and felt she had a continually surprised look. She requested correction of the eyebrow position. We performed a "reverse brow lift," with mobilization of the forehead in the subcutaneous plane and release of the periorbital ligaments through an endoscopic approach and suture fixation of the medial brow through an upper lid blepharoplasty incision. The patient was very pleased with the improvement of the eyebrow shape; the medial portion of the brow had been moved more caudally, correcting her constant surprised appearance.

This patient had undergone a primary face lift 10 years earlier. She now expressed concern about her continued facial aging and obvious scars. The secondary procedure was designed to elevate the postauricular scars up higher behind the ear and restore the gap in the hairline, elevate the midface, and tighten the neck; an endoscopic brow lift was also performed. She is seen 4 years postoperatively.

Concluding Thoughts

Facial reoperative conditions vary, depending on the patient's altered anatomy and concerns. This may include the need to correct complications such as hematoma and nerve injury. Adjunctive procedures are becoming more numerous and are being used to a much greater extent today. Staged procedures in which the patient may need early intervention can be anticipated or can be used to delay more definitive face-lifting procedures. Improving the results of dissatisfied primary facial rejuvenation patients can represent some of the more challenging cases; it can be difficult to achieve results that both the surgeon and patient will accept. The most common reason for reoperation is for the continued stigmata of aging.

It is important to make an accurate preoperative diagnosis and then design the reoperative plan. The surgeon can retain patients in the practice by advising them regarding ways to maintain their results, such as skin care, neurotoxin therapy, dermal fillers, laser skin resurfacing, and ultimately, additional surgical procedures.

Clinical Caveats

The surgeon must educate the patient about the fact that a face lift does not last forever.

It is a mistake to conclude that every patient must have your definitive procedure, as if the surgeon who performed the primary procedure lacked your skill.

Attend to what bothers the patient about his or her face: listen to the patient!

In a secondary procedure, there may be asymmetries resulting from the primary procedure, and anatomic differences: the facial nerve may be in a different place.

It is very important to determine exactly what was performed in the previous procedure, and in what plane.

Because there has been increasing emphasis on the midface and volumetric shaping in recent years, these issues might not have been addressed in the patient's initial face lift.

Patients with poor-quality skin and/or heavy tissues should be counseled that a staged procedure may be necessary to achieve optimal results.

Men have a higher incidence of hematoma after surgery, probably because of the increased vascularity of male facial skin.

Annotated Bibliography

Baker DC, Chiu ES. Bedside treatment of early acute rhytidectomy hematomas. *Plast Reconstr Surg* 115:2119-2122; discussion 2123, 2005.

The authors describe their technique for management of hematomas following face-lift surgery using an emergency "hematoma kit" at the bedside with monitoring while the patient is under sedation with analgesia. Contraindications are also discussed, such as delayed diagnosis, bilateral hematoma, and airway compromise. With close perioperative monitoring and early diagnosis and treatment, costly returns to the operating room can be minimized.

Baker DC, Stefani WA, Chiu ES. Reducing the incidence of hematoma requiring surgical evacuation following male rhytidectomy: a 30-year review of 985 cases. *Plast Reconstr Surg* 116:1973-1985; discussion 1986-1987, 2005.

This is an excellent, well-written, well-organized, comprehensive retrospective study on the incidence of hematoma in male rhytidectomy patients. The authors have provided an in-depth analysis of the causative factors and recommended therapeutic and preventive measures for management of this most common adverse event, including a very practical table of commonly used medication in the perioperative period.

Guyuron B. Secondary rhytidectomy. *Plast Reconstr Surg* 114:797-800, 2004.

Sequelae such as malposition of the sideburn, earlobe deformity, hypertrophic scars, loss of tragal definition, uncorrected marionette lines, and neck contour irregularities are often associated with secondary rhytidectomy. The author discusses some of his methods for the prevention and correction of these problems and guidelines for laser skin resurfacing combined with rhytidectomy.

Jones BM, Grover R. Avoiding hematoma in cervicofacial rhytidectomy: a personal 8-year quest. Reviewing 910 patients. *Plast Reconstr Surg* 113:381-387; discussion 388-390, 2004.

The authors examined the effects of various parameters (dressings, drains, fibrin glue, and tumescent infiltration, with and without epinephrine) on the rate of hematoma in this large consecutive retrospective study. Only the omission of epinephrine significantly decreased the hematoma rate. An incisive critical analysis of their results by the discussant suggests the restoration of normal blood pressure and other factors may be more instrumental in achieving a low complication rate.

Matarasso A, Elkwood A, Rankin M. National plastic surgery survey: face lift techniques and complications. *Plast Reconstr Surg* 106:1185-1195; discussion 1196, 2000.

Trends in the techniques used in rhytidectomy and complication rates and management of complications among American plastic surgeons were surveyed. The conclusions drawn were somewhat challenged by a 15% response rate, which was nonetheless statistically significant. The discussant added conventional wisdom to this ambitious project.

CHAPTER 50

Avoiding Complications in Facial Aesthetic Surgery

FOAD NAHAI

The only surgeons who have no complications are those who do not operate, or those who deny having complications. The rest of us take measures and make every effort to minimize our complications. The overall complication rate for facial aesthetic surgery is reported to range from 1% to 10%; this rate is a little higher in men.

Data from the American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF) reported by Keyes et al in 2008 included four deaths from face lifts and related procedures. These deaths were caused by venous thromboembolism (VTE) or oversedation and were associated with face lifts in combination with other procedures. Our Paces Plastic Surgery 4-year review of 468 face lifts showed a complication rate of 3.6% in patients who underwent face lifts and blepharoplasties. However, when an additional procedure was performed, this incidence almost doubled to 6.2%, and if two or more procedures were added to the face lift, the incidence more than quadrupled to 14.9%.

The list of potential complications includes the following:

- Hematoma
- Hair problems
- Skin necrosis
- Scars
- Contour irregularities
- Ear deformities
- Nerve injury
- Seroma
- Infection
- Parotid fistula
- Venous thromboembolism
- Death

Hematoma is by far the most common complication, accounting for almost 70% of all face-lift complications. Some complications are rare, some are devastating, and still others are not true complications but rather quality or craftsmanship (“finesse”) issues.

Common complications include hematoma and temporary nerve paralysis. Devastating complications include unrecognized or untreated hematomas, skin slough, permanent nerve injury, and VTE. Although an expanding hematoma is not uncommon, an unrecognized or untreated hematoma is a real disaster that can lead to significant skin necrosis or even airway compromise. Finesse issues include unfavorable results, un-

sightly scars, ear distortions, hairline distortions and hair loss, and contour irregularities. Unusual complications include seroma, parotid fistula, and infection.

In terms of litigation, face lift ranks number five among aesthetic procedures, representing 9% of the total number of lawsuits filed, according to data from The Doctor's Company (Napa, CA) for 1997 to 2002.

Avoiding Hematoma

The incidence of hematomas with face lifts ranges from 1% to as high as 10%. According to data from the AAAASE, hematoma after a face lift and related procedures managed on an outpatient basis ranked only second to hematoma after breast augmentation and revision and second to abdominoplasty for hematomas managed on an inpatient basis. The incidence in men and in patients with a history of hypertension is significantly higher.

Steps to minimize the risk of hematoma are taken before, during, and immediately after the operation. Preoperative measures include a workup and control of blood pressure and instructing the patient to avoid medications, dietary supplements, and herbal remedies that may affect bleeding. There have been recent reports that some antidepressants may play a role in the development of hematomas after face lifts. We encourage our patients to take supplements of vitamin C to minimize bleeding problems. All men are questioned about prostatic symptoms, and it is essential that such symptoms be controlled before a face-lift operation.

MEDICATIONS TO AVOID BEFORE SURGERY

Do not take vitamin E, garlic tablets, weight-loss products, aspirin, or aspirin products for 1 month before surgery, because these may promote bleeding.

If you are taking warfarin (Coumadin): Please notify us immediately; you must also contact your physician who prescribed this drug. He or she will need to make the decision as to whether you can be taken off this drug for surgery and will need to provide a written medical clearance.

ASPIRIN products include:

Alka-Seltzer
Anacin
Ascriptin
Bayer
BC Tablets
Bufferin
Cheracol
Cope
Coricidin
Darvon Compound
Dristan
Ecotrin
Empirin
Excedrin
Fiorinal
Midol
Percodan
Sine-Aid
Sine-Off
Soma Compound
Stendin
Triaminicin
Vanquish

IBUPROFEN medications include:

Advil
Alleve
Medipren
Motrin
Nuprin
Rufen

ANTIARTHRITIC medications include:

Anaprox
Ansaid
Butazolidin
Clinoril
Daypro
Dolobid
Feldene
Indocin
Naprosyn
Orudis
Relafen
Tolectin
Voltarin

DIETARY SUPPLEMENTS include:

Echinacea
Ephedra
Garlic tablets
Ginko biloba
Ginseng
Kava
St. John's wort
Valerian
Vitamin E

Please take only acetaminophen (Tylenol) for pain before your surgery.

We encourage you to take 2000 to 3000 mg of vitamin C every day before your surgery and during the recovery to alleviate bruising and swelling resulting from the surgery.

Intraoperative measures include close cooperation between the anesthesiologist and the surgeon. When these two work as a team, the incidence of hematoma can be significantly reduced. Rigorous control of blood pressure during the procedure is important. The actual blood pressure, whether high or normal, is not as important as avoiding fluctuations in blood pressure. A report by Jones and colleagues suggested that postoperative hematoma might be related to the rebound effect through the use of vasoconstrictors; they recommended that vasoconstrictors be avoided. However, I still inject vasoconstrictors and rely on meticulous hemostasis. Appropriate fluid management during the procedure is also important. We routinely place a Foley catheter for procedures taking 4 hours or longer so that the patient will not have a full bladder in the recovery room.

The routine use of clonidine (a long-acting alpha-2-adrenergic blocker with central and peripheral effects) has been advocated perioperatively to control the systolic blood pressure. Most if not all of my patients undergo face lifts under general anesthesia, and I do not initiate clonidine therapy before the operation. All male patients are routinely treated with oral clonidine in the recovery room, and if need be, with parenteral antihypotensive agents until the clonidine becomes effective. Women are given clonidine on an individual basis.

I think the immediate postoperative period is the most critical for avoiding hematoma. In my experience most hematomas occur in the recovery room or within the first 12 to 18 hours postoperatively. Although delayed (up to 3 weeks) hematomas have been reported, these are most likely caused by bleeding from the superficial temporal or other relatively large vessels. Close monitoring and observation in the recovery room and during the first 12 hours postoperatively is the key to minimizing hematoma.

Patients are monitored for pain, anxiety and agitation, blood pressure elevation, restlessness, nausea and vomiting, and a full bladder. Aggressive control and treatment of each of these will significantly reduce the incidence of hematoma. Therefore, in all our male patients, in addition to clonidine, we administer postoperative sedation and antianxiety medication. Selectively in female patients, we do the same. I have found that by working with the same anesthesia team, the same operating room team, and the same recovery room team, the incidence of hematoma in my personal practice has been significantly reduced. When I was in practice at a university medical center, I did not always work with the same team in the operating room, nor did the same team always take care of my patients in the recovery room. During that time, the incidence of hematoma in my patients was 6%; over the past years that I have been in private practice, always working with the same team, the incidence has been lowered to 1% to 2%. This parallels the experience reported by Baker et al in private practice, after they instituted the guidelines that we have since adopted.

Sequential or repeated hematomas may indicate an underlying deficiency in the blood-clotting system. Even a bilateral hematoma may point to blood-clotting problems. We routinely review the patient's platelet count and solicit a history of bleeding tendencies, hematoma, or prolonged bleeding associated with previous dental or surgical procedures. In patients with unusual bleeding during the procedure or those with sequential or bilateral hematoma, administration of desmopressin acetate (DDAVP) has proved effective. The recommended dose is 0.3 $\mu\text{g}/\text{kg}$ given intravenously over a 10-minute period.

Management of Hematoma

Expeditious and appropriate management of hematoma will minimize its consequences. Immediate decompression of an expanding hematoma in the recovery room or at the bedside can often defuse the situation. Patients with expanding hematomas are agitated, apprehensive, fearful, and in pain. Cutting the sutures and inserting a gloved finger or sterile instrument will deliver the clots, relieving some of the tension, pain, and anxiety. Baker and colleagues advocate not only drainage but also complete management of face-lift hematomas at the bedside. I prefer to take the patient back to the operating room for exploration and control of the hematoma rather than trying to deal with it in the recovery room or at the bedside. Once the hematoma has been decompressed, there is time to call a team if needed and prepare an operating room. In the operating room, with the patient under general anesthesia (if appropriate), or otherwise under sedation and local anesthesia with full monitoring, enough sutures are removed to allow access. If need be, all of the sutures are removed. I resist the temptation to trivialize the hematoma and to minimize my treatment of it. Once the wound has been adequately opened, all of the clots are evacuated. A di-

lute 10% solution of hydrogen peroxide is useful in breaking up the clots. The wound is thoroughly explored, and sometimes no actual source of bleeding is identified. If a source of bleeding is identified, it is suture-ligated or cauterized as needed. The open wound is then observed for any further evidence of bleeding and then closed over a suction drain.

Management of Hematoma

- Remove sutures
- Evacuate all clots
- Irrigate with dilute peroxide to break up clots
- Close over drains

This patient, whose primary face lift was performed elsewhere, developed a small localized hematoma in her right cheek. This was initially observed and was aspirated at a later date. It has left her with a contour irregularity.

I have emphasized that an undrained, expanding hematoma can lead to disastrous skin slough or even airway compromise. Even a small undrained hematoma will lead to problems such as contour irregularities, prolonged ecchymosis, prolonged swelling, seroma, and scarring. I prefer to open and drain all postoperative hematomas, regardless of size, to minimize these sequelae.

In the final analysis, it is unlikely that hematomas can be totally eliminated. However, experienced surgeons, anesthesiologists, and operating room and recovery room nurses can reduce the incidence of hematoma to 1% by focusing on details.

Avoiding Skin Slough

Skin slough most commonly results from tension on the skin rather than direct vascular compromise. The two most common causes of tension are tight closures and expanding hematomas. Factors leading to underlying circulatory problems that can increase the risk of hematoma include smoking, acne scarring, and diabetes. Unusual and devastating infections may also lead to skin necrosis.

Skin sloughs are minimized through measures taken before, during, and after the operation. High-risk patients, including smokers and those with acne scars, are identified preoperatively. Smokers are advised to stop smoking 3 or 4 weeks before and after surgery. However, it is impossible without a urine test to establish that patients have followed directions, because they all claim to have done so; I do not routinely ask for a urine test to confirm that the patient has ceased smoking. These high-risk patients are also started on systemic and local antioxidants, such as oral and topical vitamin C. The surgical approach to these patients is modified. Skin incisions, planes of dissection, and the extent of skin undermining are significantly altered in high-risk patients. Whenever possible, skin incisions are minimized and modified to avoid long retroauricular flaps. Skin undermining is limited and deeper planes of dissection, such as subperiosteal, subgaleal, and sub-SMAS, are preferred. I have found the short-scar face lift, which limits retroauricular incisions or undermining, is a good option in smokers. In some smokers I recommend a two-stage procedure to achieve an excellent result. I explain to all of them that given the restraints on the degree or extent of undermining, they should not expect an outstanding result. Concomitant skin resurfacing is restricted to the areas that have not been undermined or is postponed for a later time. Heavy or tight dressings are avoided, and the tissues are kept moist through the judicious use of petrolatum-based ointments. Postoperatively, a strict no-smoking policy is strongly emphasized.

Treatment of Skin Slough

The early treatment of skin ischemia or a pending slough is reduction of tension by removing the sutures. If necessary, Nitrol nitroglycerin cream is applied to the compromised flap. In the rare patient in whom infection is the cause of sloughing, the infection is aggressively treated. Hyperbaric oxygen has been advocated for the treatment of face-lift flap compromise and necrosis. This may well be an option, especially in a patient who smokes. Long-term treatment of skin slough requires patience from the surgeon and the patient. The surgeon must show a great deal of understanding and must frequently reassure the patient that eventually all of the wounds will heal. It is best to allow open wounds to heal secondarily and to deal with the consequences once the wound is healed. Late treatment of skin slough includes compression, topical agents, steroid injection, and eventually scar revision or even secondary procedures.

This patient had a full-thickness skin loss after a staphylococcal infection. She was treated conservatively, and the area was kept moist. It had almost completely closed through contraction and spontaneous reepithelialization by 6 weeks. The resultant scar matured sufficiently so that no scar revision was necessary.

Nerve Injuries

Motor branches of the facial nerve and sensory nerves, mostly branches of the trigeminal nerve, are at risk during face lifts. Rare and unusual injuries to the accessory nerve have been reported.

Sensory Nerves

Sensory nerve injuries in facial aesthetic surgery are uncommon and are rarely of serious consequence. The great auricular nerve is at risk during standard face-lift procedures; the supraorbital, supratrochlear, and zygomaticotemporal nerves are at risk during brow lifts; the infraorbital nerve is at risk during subperiosteal midface lifts and during the placement of cheek implants; the zygomaticofacial nerve is at risk during subperiosteal midface procedures; and the mental nerve is at risk during chin augmentation.

The great auricular nerve is most at risk during face and neck lifts. It emerges around the posterior border of the sternocleidomastoid muscle at McKinney's point, 6.5 cm below the external auditory meatus, and courses almost directly upward to the ear-

lobe. The surgeon can avoid injury to this nerve through knowledge of its anatomy and cautious flap elevation over the sternocleidomastoid muscle. Leaving the sternocleidomastoid fascia intact will usually protect this nerve. It is advisable in secondary face and neck lifts to perform this dissection under direct vision rather than blindly, because the preexisting scar tissue may distort the planes of dissection. Injury to the nerve will lead to numbness of the lower two thirds of the ear. This sensory loss is not debilitating, but a painful neuroma of the greater auricular nerve can be. If an injury to the nerve is recognized, the surgeon should attempt to repair it with the aid of magnification. If this is not possible, the proximal stump should be buried well within the sternocleidomastoid muscle to prevent a neuroma. Painful great auricular nerve neuromas are rare, and even more rarely these neuromas may present as a neck mass and be mistaken for an enlarged lymph node.

The supraorbital nerve emerges from the orbit through a notch or a foramen, usually in the midpupillary line, and provides sensory innervation to nearly half of the forehead and anterior scalp. The lateral branch, which courses along the temporal crest, is responsible for most of the innervation of the anterior scalp. Injury to the supraorbital nerve during endoscopic brow lift is rare. However, the surgeon must be aware that this nerve can emerge through a foramen up to 2 cm above the orbital rim, so blind dissection should be limited to a distance of 2 to 4 cm above the orbital rim, and the orbital rim should be approached endoscopically to avoid nerve injury. The lateral sensory branch of the orbital nerve is almost always divided during a transcoronal brow lift, resulting in forehead sensory loss, paresthesias, and dysesthesias. These sensory changes, fortunately, are usually temporary but can be permanent.

The supratrochlear nerve has multiple branches and emerges through the orbit medially within 1 or 2 cm of the midline and usually courses within the corrugator muscle. It provides sensory innervation for a narrow strip of medial forehead and brow on each side. During an endoscopic brow lift, one or two branches of the supratrochlear nerve may be disrupted during the corrugator muscle excision. This is rarely of any clinical significance.

The zygomaticotemporal nerve is a very small nerve that emerges through the temporal fascia, usually accompanying the lateral of the two sentinel veins. When viewing this nerve during an endoscopic brow lift, I make every attempt to preserve it, although injury to the nerve is of little consequence.

The infraorbital nerve emerges through a foramen 1 or 2 cm below the inferior orbital rim in the midpupillary line and innervates the cheek, lips, and teeth. It is rarely at risk during subcutaneous or sub-SMAS face-lift procedures. It is at greatest risk during subperiosteal midface dissections, whether through the mouth, lower eyelid, or temporal area. However, injury to this nerve is extremely rare, because it is very large, easily identified with or without an endoscope, and difficult to injure with a periosteal elevator.

The zygomaticofacial nerve is a small nerve that emerges through a foramen 1 to 2 cm lateral to and below the lateral canthus. It is only at risk during subperiosteal dissection of the periorbital area. Unlike the infraorbital nerve, the zygomaticofacial nerve is very small and very easily divided. It is always accompanied by a small blood vessel, and often the only indication that the nerve has been divided is the bleeding. I make every attempt to identify and preserve this nerve during subperiosteal mid-face lifts. Division of the nerve is of little consequence in terms of sensory loss, but irritating discomfort in the area has been attributed to division of the nerve.

The mental nerve emerges through the mandible in the midpupillary line at the level of the second premolar. This nerve is at risk during subperiosteal dissection for placement of chin implants. Fortunately, it is a large nerve that is easily identified and not easily injured with a periosteal elevator. Injury to the nerve results in debilitating sensory loss in the lips and teeth.

Motor Nerve

One of the most devastating and long-lasting complications after facial rejuvenation surgery is permanent injury of a branch of the facial nerve. Fortunately, the incidence of facial nerve paralysis is fairly low. In a reported series of 6500 patients, facial nerve paralysis was seen in 0.7%, with only 0.1% permanent. With endoscopic brow lifts, the incidence of temporary paresis to the frontal branch of the facial nerve has been consistently reported at 1%, with permanent injury of 0.1%. My personal experience parallels these reported series, but I have been fortunate enough not to have permanent paralysis in any of my patients.

The facial nerve branches most at risk include the buccal, frontal, and marginal mandibular branches. Recently concern has been raised about the zygomatic branches in association with complex periorbital procedures.

Most commonly reported injuries involve the buccal branches; however, because these are multiple branches rather than a single nerve, recovery is usually seen within 3 to 4 months. The frontal branch is the next most frequently reported injured nerve, and these are also multiple branches rather than a single nerve, and recovery is the rule; however, recovery takes longer than after buccal branch injury. The marginal mandibular branch is a single nerve, and complete recovery after injury is rare. Fortunately, the resulting asymmetry of the mouth can be improved through the judicious administration of *botulinum* toxin on the opposite side.

Buccal and Zygomatic Branches

The buccal branches are multiple, and injury to all branches is rare. Dissection below the SMAS, beyond the parotid gland, puts these nerves at risk. Therefore in any face-lift procedure necessitating sub-SMAS dissection beyond the parotid gland, the dissection should be performed bluntly and with caution. These branches are readily visible, and injury is easily avoided. Blind or sharp dissection beyond the parotid gland should be avoided. These branches all run deep to the zygomaticus major muscle, so dissection beyond the zygomaticus major toward the nose and nasolabial fold is safe as long as it is in a plane above the zygomaticus major.

Frontal Branches of the Facial Nerve

The frontal branches of the facial nerve are at risk not only during forehead lifts (coronal and endoscopic) but also with sub-SMAS face lifts, especially techniques requiring a high-SMAS dissection. Classically the landmark for identifying the course of this nerve has been a diagonal line drawn from a point 5 mm below the tragus to a point 2 cm above the lateral brow. However, I have found that if the sentinel vein is visible through the skin, a point 5 mm above the vein will usually mark the course of the vein. I then draw a diagonal line toward the tragus and use this as the guideline. Because this nerve runs under the temporoparietal fascia above the zygoma and very deep to the SMAS, below the zygoma, the surgeon can avoid injury to the nerve by performing the temporal dissection of any forehead lift well below the temporoparietal fascia. In fact, I make a point of placing all of my instruments directly over the deep temporal fascia, pushing on the fascia as I dissect toward the zygoma and orbital rim. Below the zygoma, injury is avoided by staying above the SMAS. However, if high sub-SMAS dissection is undertaken, injury to the nerve is avoided by dissecting just below the SMAS. Recent anatomic data demonstrate that the nerve lies much deeper and closer to the periosteum of the zygoma rather than just below the SMAS. During a combined temporal and facial dissection, the development and maintenance of a “mesotemporalis” made up of the temporoparietal fascia and SMAS will ensure the safety of this nerve.

Marginal Mandibular Branch

Although the marginal mandibular branch is deep to the SMAS and the platysma along all of its course, it is still susceptible to injury, especially as it courses over the facial vessels at the level of the mandibular notch. The two factors contributing to this area of risk are (1) the thinning of the SMAS and platysma in that area and (2) the presence of perforating branches of the facial vessels. The thinning of the SMAS and platysma puts the nerve at risk during blind dissection, where the scissors can easily slip through the thin platysma and injure the nerve. The other mechanism of injury is the use of electrocautery in an attempt to control bleeding from the perforating vessels. As a general rule, I prefer to use bipolar rather than the unipolar coagulating current for hemostasis during facial rejuvenation, because there is less electrocautery current that can damage the nerve. In thin individuals I prefer to perform the dissection along the mandibular border under direct vision to minimize the risk of subplatysmal penetration.

When performing subplatysmal dissection of the neck, the surgeon must keep in mind that the relationship of the marginal mandibular branch to the inferior border of the mandible is variable; in fact, it can run 1 to 2 cm below the mandible along its entire course, not just proximal to the facial vessels and the mandibular notch.

FACIAL DANGER ZONES: MOTOR AND SENSORY NERVES

Although permanent injuries to the branches of the facial nerve are rare, it is vital that the surgeon be familiar with the anatomy of these branches, their relationships to the various layers of the face, their specific danger zones, and the risk afforded each branch by the more complex and deeper dissections. Familiarity with specific techniques is essential to minimize risk and avoid complications. I encourage anyone performing facial rejuvenation to dissect the layers of the face and branches of the facial nerve in the cadaver laboratory.

Spinal Accessory Nerve

Although extremely rare, injury to the spinal accessory nerve and a resultant shoulder drop have been reported. The nerve is most at risk during posterolateral dissection in the neck. The nerve emerges behind the posterior border of the sternocleidomastoid, almost at McKinney's point or just above, coursing posteriorly and laterally toward the trapezius.

Deep Venous Thrombosis

Venous thromboembolism (VTE) and its consequences, deep venous thrombosis (DVT) and pulmonary thromboembolism (PE), are devastating, life-threatening, and fortunately uncommon. The exact incidence of DVT in facial aesthetic surgery is not known. Reinisch et al reported an incidence of 0.35% for DVT and 0.14% for PE in face lifts. A 4-year review of 468 face lifts at Paces Plastic Surgery revealed two patients with DVT, an incidence of 0.4%, with no PE. Our 0.4% compares to the 0.35% reported by the Reinisch group. Spring and Gutowski surveyed 3797 plastic surgeons in the United States, who reported 15 DVT and PE events associated with facial cosmetic procedures. Every precaution should be taken to minimize the risk of DVT. Factors increasing the risk include the following:

Age	Family history
Weight	Use of oral contraceptives
Length of procedure	Type of anesthesia

Based on these factors, the dual task force of the American Society of Plastic Surgeons (ASPS) and the American Society for Aesthetic Plastic Surgery (ASAPS) assigned risk categories and made recommendations for patients undergoing plastic surgery procedures according to the assigned risk category. These recommendations were published in the November 1999 issue of *Plastic and Reconstructive Surgery*. They are summarized in the table on p. 1778.

DVT Prophylaxis

Risk Factors	Recommendations
Low Risk <41 years of age No oral contraceptives/hormones No chronic disease, infections, malignancy No personal or family history of DVT, PE, etc. No history of venous insufficiency Short operative procedure	Comfortable position on operating table Slight knee flexion Avoid extremity compression or constriction
Moderate Risk >41 years of age Current oral contraceptives/hormones Chronic disease, infections, malignancy Personal or family history of DVT, PE, etc. Short operative procedure	Comfortable position on operating table Slight knee flexion Avoid extremity compression or constriction Intermittent pneumatic compression Frequent alteration of operating table position
High Risk >41 years of age Longer procedure (>1 hr) Current oral contraceptives/hormones Chronic disease, infections, malignancy Personal or family history of DVT, PE, etc.	Comfortable position on operating table Slight knee flexion Avoid extremity compression or constriction Consider preoperative hematology consultation Consider preoperative and postoperative anticoagulants Intermittent pneumatic compression

From McDevitt NB. Deep vein thrombosis prophylaxis. American Society of Plastic and Reconstructive Surgeons. *Plast Reconstr Surg* 104:1923-1928, 1999.

Standard pneumatic pressure garments extending from knee to ankle

PlexiPulse intermittent pneumatic compression devices (Kinetic Concepts, Inc., San Antonio, TX) placed on feet

In my practice almost all patients undergoing facial rejuvenation fall into the high-risk category. All of these patients are operated on under general anesthesia; support is placed behind their knees, and intermittent pneumatic compression garments are used in all of them. Stuzin et al have reported zero incidence of DVT in over 10,000 face lifts spanning 30 years, all of which were performed under local anesthesia with sedation. They comment that patients operated on with intravenous sedation moved during the procedure thus reducing the tendency of venous stasis and DVT.

Venous Thromboembolism Risk Factors for Plastic Surgeons to Consider

*Solid, consistent evidence that these are the most important risk factors**

Prior history of VTE (DVT or PE)
 Malignancy (active or in patient history)
 Thrombophilia disorders (inherited or acquired)
 Factor V Leiden mutation (makes factor V resistant to activated protein C)
 Prothrombin 20210A mutation (found exclusively in whites)
 Antithrombin deficiency
 Protein S and protein C deficiency
 High levels of fibrinogen or plasminogen, factor VIII, factor IX, factor XI, thrombin activatable fibrinolysis inhibitor (TAFI), or protein C inhibitor
 Low levels of tissue factor pathway inhibitor (TFPI)
 Hyperhomocysteinemia (plasma homocysteine level >18.5 mmol/L)
 Dysfibrinogenemia and polycythemia vera
 Antiphospholipid antibodies (lupus anticoagulant and anticardiolipin)
 Obesity (risk may be highest for those <40 years of age)
 Use of oral contraceptives, tamoxifen, hormone replacement therapy, or other estrogen-containing drugs

Known to be risk factors but probably not in the top tier; do not disregard as unimportant

Age $\geq$ 40 years (risk rises as age rises)
 General anesthesia (risk rises with each hour in surgery, regardless of procedure)
 Varicose veins
 Inflammatory disease (inflammatory bowel disease, rheumatologic diseases, especially systemic lupus erythematosus)
 Abdominal surgery (carries higher risk than most other types of surgery)
 Pregnancy, abortion, or miscarriage within 3 months
 Smoking
 Recent hip or knee replacement or hip fracture
 Recent surgery of any kind
 Prolonged travel by air, train, or car
 Recent physical trauma

*Important risk factors that are rarely encountered in plastic surgery practices include prolonged immobilization, ischemic stroke, heart failure, chronic lung disease, respiratory failure, serious infection, pneumonia, central venous catheterization, paralysis, spinal cord injury. Some risk factors are permanent (such as a history of VTE or cancer, chronic disease, thrombophilia, age) and some are transient (such as surgery, travel, estrogen use, pregnancy).

Craftsmanship Issues

Some postoperative concerns are not true complications; I prefer to call them issues of finesse, quality, or craftsmanship. But they are the issues that make all the difference in the patient's perception of the quality of the result. In this category I include the following:

- Scar placement and scar quality
- Ear distortion
- Hair loss and hairline distortion
- Contour irregularities

Scar Placement and Scar Quality

I regularly talk to patients to explain where the incisions and scars will be. Occasionally the patient looks back at me and comments, "Well, there won't be any scars, will there? This is plastic surgery, after all." I reply that all incisions leave scars and that the best I can offer them is to place the scars where they will be imperceptible or at least less noticeable, and that I will make every effort to ensure the quality of the scars, although this will depend as much on the location and tension as well as on the patient's biology as it will on surgical technique.

Avoiding Undesirable Scars

The key to avoiding undesirable scars is to manage tension appropriately. Special attention is required in those who are prone to hypertrophic scarring, especially red-headed individuals with a ruddy complexion and patients who are keloid prone.

This man underwent a MACS-lift elsewhere and has hypertrophic scars in front and behind his ear, most likely related to tension. Note that the horizontal scar below his sideburn has healed well. Incisions are planned so that they will be inconspicuous and allow appropriate distribution of tension. Meticulous closure under mini-

mal tension and aggressive early management of scar problems are important. Incisions in the hair are made parallel to the hair roots; the use of cautery is judicious and limited to preserve hair roots. Closure must avoid excessive tension, which damages the hair roots. Incisions along the hairline are also made in the direction of the hair roots to preserve and encourage hair growth through the resulting scar.

The preauricular incision should never be a straight line. It should be broken up above and below the tragus. I prefer the intratragal incision whenever possible.

This incision is made in such a way that the tragus has a beginning and an end. Far too often this is not done, and the tragus blends into the lower face with a telltale sign of a face lift. The incision behind the ear is placed either within the sulcus or 1 to 2 mm on the posterior surface of the ear. My preference is to make it on the ear rather than within the sulcus.

This woman underwent a face lift by a nonsurgeon who left her with a hypertrophic straight-line scar in front of her ear and little in the way of facial rejuvenation. I saw her in consultation and performed a secondary face lift with appropriate placement of the incisions. Seven years later, the tragus appears natural and there is no hypertrophic scarring or distortion. In the intervening 7 years she has colored her hair.

Distribution of tension during the closure defines the quality of the resultant scar. Tension should usually be placed at the level of the concha, behind the earlobe, and behind the ear, never in the preauricular or tragal area or the earlobe. Once the skin tension has been appropriately distributed, the excess skin along the preauricular area and behind the ear is excised and closed in two layers under no tension. Usually this closure will not require a suture any larger than a 6-0. If sutures stronger than 6-0 are required for this closure, then there is too much tension and the scar will widen unacceptably.

This patient, who had a face lift with the full classic incision including preauricular intratragal incisions, is seen preoperatively and in early postoperative and late postoperative views.

Preoperative and 4-year postoperative views of a patient who underwent a short-scar face lift with a preauricular intratragal incision ending at the earlobe.

Closure of the retroauricular incision requires as much attention to detail or perhaps even more than the preauricular incision. It is very unusual to see hypertrophic scarring in front of the ear; however, it is not so uncommon to see it behind the ear. I think this is related to excessive tension and overresection of retroauricular skin. Another problem is scar migration in an outward direction from the retroauricular sulcus. This is avoided by anchoring the posterior ear skin and the face-lift flap skin to the mastoid fascia with every bite or every other bite when closing the retroauricular portion of the incision.

Treatment of undesirable scars includes intralesional injection of steroid medications and the application of topical creams or silicone gels. Scar revision may also be an appropriate treatment.

Ear Distortion

Very often, close observation of the tragus and earlobe will reveal telltale signs of a face lift. It is not only the appearance of the scar but distortions of the tragus and earlobe that attract the eye and scream out: "*Yes, I have had a face lift!*"

The tragus must have a beginning and an end, and must project outward from the face and external auditory meatus with a gentle posterior tilt. Forward displacement renders the external auditory meatus more visible, creating the impression that it has been enlarged. This is a result of excessive tension with no break above or below the tragus. An extreme example is the ablation of the tragus. This is avoided by deepening the pretragal sulcus, especially in secondary face lifts and, if necessary, suturing the pretragal skin into the sulcus.

This patient who has had a previous face lift demonstrates near complete ablation of her tragus with wide open external auditory meatus. Her earring conceals the pixie ear deformity. On the right, her ear is seen on the operating table before a secondary face lift.

Earlobe problems are related to improper closure around the earlobe. I prefer to leave the earlobe hanging free rather than suturing it to the skin flap. This allows the natural “angle of the dangle” described by Connell. Suturing the earlobe leads to pixie earlobe deformity and a migration of the earlobe into the neck, another telltale sign of a face lift.

Another finesse issue with the earlobe is the concomitant reduction of the earlobe at the time of a rhytidectomy. This is especially important in older patients who have large, pendulous, creased earlobes. The addition of autologous fat or filler into the aging earlobe will eliminate the creases and render a more youthful appearance.

Hair Loss and Hairline Distortion

Hairline distortion is one of the most common stigmata of a face lift. Possible distortions include the following: elevation or elimination of the sideburns, irregular or a step-off in the retroauricular hairline, and frontal hairline elevation. The most common problem, however, is scar alopecia. This is also the simplest problem to resolve.

Sideburn elevation or elimination is avoided by appropriate placement of the incision. In a primary face lift in patients with a short sideburn, I will make a prehairline incision, and in all patients undergoing secondary face lifts I will also make a prehairline incision. This affords ample exposure for the face lift without any change in sideburn position. An alternative is to continue the preauricular incision into the temporal area and to take out the skin triangle below the sideburns. This will also maintain sideburn length.

After a previous face lift, this woman had elevation of the hairline, with elimination of sideburns and a wide, depigmented preauricular scar.

Preoperative and postoperative views are shown of a patient who had a secondary face lift. Hairline distortion and sideburn shortening was avoided through a prehairline incision extending into the preauricular, intratragal, and retroauricular areas.

Retroauricular hairline step-offs and distortion are avoided by aligning the occipital hairline first and then resecting the excess retroauricular skin and scalp. A certain amount of tailoring is needed in patients with excess or loose neck skin.

The high-forehead hairline is seen more commonly with coronal rather than endoscopic brow lifts, although brow elevation is also seen with the endoscopic approach. This problem is best avoided by techniques that allow shortening of the forehead; all of these techniques entail an incision in the frontal hairline, an incision that some patients are not willing to accept.

Scar Alopecia

Hair loss is avoided through minimization of tension and with gentle tissue handling. Overuse of the electrocautery, tight sutures, and staples will damage hair roots. The

most common scar alopecia that I have encountered has been at the external screw fixation site associated with the endoscopic forehead lift. All of these problems are relatively easy to correct through simple excision of the bald spots under local anesthesia.

Very rarely, after facial aesthetic surgery and brow lift (notably endoscopic brow lift), there may be partial or full alopecia of the entire scalp. Fortunately, most of these are self-limiting. Topical use of Rogaine and steroids may accelerate the recovery. In patients with thinning hair, as a preventive measure I encourage the preoperative and postoperative use of Rogaine on the scalp.

Contour Irregularities

Contour irregularities result from improper defatting, SMAS plication, and mismanaged hematoma.

Oversuction or suction too close to the dermis, especially in the neck, will lead to banding and skin adhesion to the platysma. This is best avoided by leaving 3 to 5 mm of fat on the deep surface of the skin, keeping the suction cannula hole pointed away from the dermis, and limiting the number of passes in each tunnel.

Excessive fat removal in the subcutaneous plane to mask or correct problems deep to the platysma is a common error that is often difficult to reverse as is seen in this woman. Overaggressive fat removal from her neck and submental area has unmasked platysma bands and prominent digastric muscles.

SMAS plication with or without SMAS resection can lead to contour irregularities. Multiple sutures should be placed to ensure that the plication and suture lines are smooth without any discernible irregularities. These are best avoided by inspecting and ensuring a smooth subcutaneous contour before closure.

Even the smallest hematoma, if inadequately drained, will lead to prolonged swelling, subcutaneous scarring, and irregularities. These irregularities are best treated through lymphatic drainage and skin massage. I have also found external ultrasound useful, especially with the banding in the neck. Steroid injections may also be helpful. Reoperation is also an option.

Some patients refer to these contour irregularities as “waves.” There are some patients, however, in whom the waves are seen only on animation, representing what I think is an imbalance of the mimetic muscles of the cheek after deep and subperiosteal procedures. These are difficult problems to correct and may be related to disruption and reattachment of muscle origins and partial denervation.

Motion Distortion

One of the more difficult problems to correct following a face lift is the distortion observed on animation, especially in the cheek area. The cause of such distortions is not fully understood, which makes the problem difficult to correct. It is thought to be related to a change in the relationship of the muscles of facial expression with the overlying soft tissues and/or the underlying bony skeleton.

Infections

Infections after facial aesthetic surgery are extremely rare, because the face has a plentiful blood supply. However, the sequelae of infection can be serious and include skin slough and scarring. All patients undergoing facial aesthetic surgery should have their faces washed and hair shampooed with antiseptic hair shampoo on the day of the procedure. The face and hair should be prepared and draped as with any other surgical procedure. Although controversial, I still use perioperative antibiotics on all patients undergoing facial aesthetic surgery.

Very rarely, *Pseudomonas* infection of the face is seen in swimmers who harbor *Pseudomonas* organisms in their auditory canals. As a precaution, we always soak the earplugs in povidone-iodine solution (Betadine) before placing them in the external auditory meatus.

Other Rare Complications

Although perforation of the parotid gland capsule or even the gland itself is encountered with sub-SMAS dissections, such violations of the gland and its capsule are very rarely of any consequence. However, a few cases of parotid fistula and even parotid cysts have been reported after rhytidectomy. If encountered, these problems are usually self-limiting and will resolve spontaneously. However, it is important to ensure that the parotid duct is intact. If the problem does not resolve spontaneously, exploration and open drainage will be required. The drug somatostatin (Sandostatin), which decreases salivary secretion, may be helpful in managing this problem. However, the side effects may not be acceptable. Injections of *botulinum* toxin A into the parotid gland will reduce its secretions and is preferred over somatostatin.

Concluding Thoughts

The results of a face lift are at best temporary. The consequences of complications may be permanent.

CLAUDIO CARDOSO DE CASTRO

Although complications cannot be totally eliminated, careful patient selection and preparation, attention to surgical and anesthesia detail, and attentive postoperative management by an experienced team will significantly reduce complications. Unlike any other field of surgery or even other areas in aesthetic surgery, complications and unfavorable results affecting the face and neck cannot be concealed or otherwise protected from public view. The problems are out there not only for you and the patient to see, but for the entire world! This is especially true for the patient's family and close friends and her hairdresser. It is vital to understand that regardless of how minor or inconsequential the problem may seem to the surgeon, these problems are significant for the patient. The patient's concerns must be openly discussed, the patient must be reassured, and every attempt should be made to rectify the problem as expeditiously as possible with minimum or no expense to the patient. After evacuation and closure of facial hematomas, I routinely reassure the patient that the hematoma will in no way affect the quality of their result but may delay their recovery, especially the resolution of the ecchymosis. Patients with temporary facial nerve paresis are reassured that in all likelihood the weakness is temporary and that permanent facial nerve weakness is extremely rare. None of us is happy about complications, least of all me. I make every attempt to personally see and take care of all my patients whenever possible. This becomes even more important with patients who have a complication. It is their own surgeon they want to see, not the surgeon's partner, assistant, or nurse. Their own surgeon should see them on every visit, and it is im-

portant that the visits become more frequent. Anything short of this will lead patients to believe that at best their surgeon is avoiding them and at worst that their surgeon has abandoned them.

Complications and patient dissatisfaction with results test not only the established doctor-patient relationship but also our abilities as physicians and compassionate human beings. The confidence and trust of the patients gained over a period of weeks, months, or even years is threatened or lost very easily if the situation is not handled sensitively.

Do not hesitate to consult partners or colleagues when dealing with complications, especially in patients who express anger or even undue concern that their problems have not been as self-limiting as you have indicated. In patients who will need extensive revisions, it is important to seek the advice of partners and other colleagues and to resolve financial issues up front and as soon as possible.

The best way to deal with complications is to avoid them. If we cannot avoid them, we must remedy them expeditiously and effectively.

Clinical Caveats

Preoperatively, patients should be given a list of medications, herbal remedies, and dietary supplements to avoid.

Appropriate blood pressure management should be initiated before, during, and after the operation to reduce the risk of hematoma.

The perioperative use of clonidine should be considered.

Pain, anxiety, nausea, and blood pressure elevation must be treated aggressively in the recovery room.

An expanding hematoma must immediately be decompressed; it is a potential disaster.

Excessive tension on the skin should be avoided.

The surgeon should be familiar with the anatomy of the sensory and motor nerves at risk.

Sub-SMAS dissection beyond the parotid gland should be done under direct vision.

Blunt instruments are best for sub-SMAS dissection beyond the parotid gland.

If possible, bipolar is preferred over unipolar coagulation of bleeders below the SMAS.

Continued

Clinical Caveats—cont'd

Preventive measures should be taken to avoid DVT in all patients.

The surgeon should be a craftsman, taking the time necessary to produce a satisfactory result.

The sideburns and hairline should be respected, keeping changes minimal.

A natural-appearing tragus and earlobe should be maintained.

The surgeon should be kind to the hair roots.

Avoid oversuction of neck fat should be avoided.

A smooth facial contour must be under the skin flap.

Complications must be treated expeditiously.

It is important to remember that the patient's facial complication is on view all the time.

Annotated Bibliography

Baker DC, Conley J. Avoiding facial nerve injuries in rhytidectomy: anatomic variations and pitfalls. *Plast Reconstr Surg* 64:781-795, 1979.

The authors discuss the detailed anatomy of the muscular branches of the facial nerve, how to prevent injuries to them during rhytidectomy, and how to manage injuries when they do occur.

Jones BM, Grover R. Avoiding hematoma in cervical rhytidectomy: a personal 8-year quest. Reviewing 910 patients. *Plast Reconstr Surg* 113:381-387; discussion 388-390, 2004.

Hematoma remains the most common complication of rhytidectomy and can lead to prolonged facial edema and skin necrosis. The authors discuss the effects of ancillary procedures and the effect of epinephrine to reduce hematoma occurrence.

Jones BM, Grover R. Reducing complications in cervicofacial rhytidectomy by tumescent infiltration: a comparative trial evaluating 678 consecutive face lifts. *Plast Reconstr Surg* 113:398-403, 2004.

This is the first comparative study of tumescent infiltration in facial rejuvenation surgery. The authors present the results of their study, which investigated the long-term outcome in a large series of consecutive face lifts performed with (229 cases) and without (449 cases) tumescence. They discuss the spectrum of techniques used in the study and compare complications between the groups. The surgical technique and aesthetic implications for rejuvenation surgery are also discussed.

Keyes GR, Singer R, Iverson RE, et al. Analysis of outpatient surgery center safety using an internet-based quality improvement and peer review program. *Plast Reconstr Surg* 113:1760-1770, 2004.

Assessing the quality of care delivered in office-based outpatient surgery centers is difficult, because formerly there was no central data collection system. The authors discuss the new Internet-based quality improvement and peer review program developed by the American Association for Accreditation of Ambulatory Surgery Facilities, which analyzes outcomes for the surgery centers it accredits. Both inpatient and outpatient sequelae are presented and compared.

McDevitt NB. Deep vein thrombosis prophylaxis. American Society of Plastic and Reconstructive Surgeons. *Plast Reconstr Surg* 104:1923-1928, 1999.

In October 1998, at the annual meeting of the American Society of Plastic and Reconstructive Surgeons, the board of directors convened the Task Force on Deep Vein Thrombosis to address concerns that had been identified through the research of the Lipoplasty Task Force. This article represents an extensive review of the literature and critical analysis of clinical experience.

McKinney P, Katrana DJ. Prevention of injury to the great auricular nerve during rhytidectomy. *Plast Reconstr Surg* 66:675-679, 1980.

The great auricular nerve is the one most commonly injured during rhytidectomy. The authors discuss a technique that uses fixed anatomic landmarks to help the surgeon avoid injury to the great auricular nerve and the jugular vein.

Rees TD, Lee YC, Coburn RJ. Expanding haematoma after rhytidectomy: a retrospective study. *Plast Reconstr Surg* 51:149-153, 1973.

Preoperative identification of patients who might be prone to hematomas, factors associated with hematomas, and measures that might be effective in their prevention are discussed.

Rees TD, Liverett DM, Guy CL. The effect of cigarette smoking on skin-flap survival in the face lift patient. *Plast Reconstr Surg* 73:911-915, 1984.

The authors present data demonstrating that a significant number of skin sloughs observed after face-lift surgery are attributed to patients' cigarette smoking. Implications in terms of patient selection and preoperative counseling are also discussed.

PART IX

REJUVENATION OF THE CHEEKS, CHIN, LIPS, AND EARS

This page intentionally left blank

CHAPTER 51

Rejuvenation of the Aging Mouth

ROBERT K. SIGAL, BYRON D. POINDEXTER,
GEORGE W. WESTON

The mouth can be a difficult area to rejuvenate. In younger patients with minimal facial aging, the surgeon can frequently leave the mouth untouched and still produce a harmonious result with standard lifting and augmentation techniques. In these patients, often in their late thirties and their forties, the focus is the midface and jawline, where well-hidden incisions under the eyes and around the ears allow re-creation of youthful contours. The surgeon may choose to fill thinning lips, rhytids, and creases or perhaps resurface the perioral skin, but often that is all that is needed. In younger patients, more is not necessarily better.

In older patients, however, ignoring the mouth often leads to facial disharmony. An old mouth in the center of an otherwise rejuvenated face does not leave the patient looking young or old—it leaves the patient looking odd. The surgeon can be left in a difficult position, with an unhappy patient and the question, “What do we do now?” There is a tendency to look back and think that if a portion of the operation had been performed “better,” the result would be different. One may wonder whether pulling harder on the midface tissues or switching to a deeper plane for the face lift might have created a better aesthetic result on a long, aging lip or loose nasolabial fold. Perhaps if more fat or filler had been added, the effect might be more natural. Although these are worthy considerations, experience suggests the result would still probably be inadequate.

Two factors conspire to defeat our efforts to rejuvenate the perioral region indirectly from the well-hidden scars around the ears or under the eyes. First is the elasticity of the facial soft tissues. Lifting techniques in any plane above the periosteum lose power the farther they are from “the pull.” Pulling the skin and SMAS a centimeter at the ear ultimately moves the nasolabial fold only millimeters. Second is the nature of the deeper tissue to which the skin is attached around the mouth. With no subcutaneous fat beneath it, the skin inside the nasolabial folds is particularly resistant to remote pull. The intimate relationship of the perioral skin to the underlying muscle tends to keep it in place. The rejuvenative efforts inside the nasolabial lines are reduced to those that are easily done; that is, erasing the wrinkles and filling the lips. Although “lipstick wrinkles” and a thin vermilion certainly deserve attention, there is often more work to be done.

This is where the utility of a direct approach to perioral aging and aesthetics is evident. Plastic surgeons are comfortable with hidden incisions on the face, and comfortable with obvious scars on other parts of the body (such as from mastopexy and abdominoplasty), but we are uncomfortable with incisions on parts of the face that might be obvious. Surgeons justifiably fear creating scars that will be visible and irreparable, a permanent reminder of the surgeon’s hand. Yet most of plastic surgery requires acknowledging and making the trade-off of a particular scar for a change in shape. As long as that trade-off is worthwhile in the vast majority of cases, a technique makes it into the arsenal of “approved” plastic surgery procedures.

Although the idea of directly excising tissue around the mouth can be daunting, we have found that direct excisions around the mouth, when placed in natural creases, are actually less noticeable than most other scars. After performing more than 3000 such direct excisions, we are convinced that they have a significant role in rejuvenating the aging mouth. In this chapter we will attempt to define our approach to restoring a youthful appearance in this difficult region.

51-1 Rejuvenation
of the aging mouth

THE AGING MOUTH

At the extremes, the differences between young and old mouths are obvious. With age, the upper lip lengthens so that the upper incisal show of youth is hidden. The lower lip attenuates and involutes, revealing the lower incisal show of age. The tissue around the oral commissure deflates and descends medially around it, producing a saddened appearance. Soft, subtle rolls are erased and replaced with angular peaks and creased valleys. The chin pad drops, and the loose tissue around the nasolabial folds becomes so excessive that it is difficult to pull flat, even in the most experienced hands. That an indirect approach to these issues is inadequate is underscored by these images: the woman on the right has already had a face lift. We will address each of these distinct signs of perioral aging with strategies for their correction.

Long Upper Lip

With age, the distance lengthens between the nostril sill and the vermilion. The upper lip thins, widens, and hangs like a curtain over the upper teeth. A youthful mouth in repose should have at least 3 to 4 mm of incisal show with the lips parted. However, recognizing the problem and fixing it are two different issues. Indirect approaches have been frustratingly unsuccessful in our hands; although some plastic surgeons claim that a midface lift will indirectly shorten the upper lip, we have been unable to duplicate their results. We have found that fat grafting alone will give a sense of lip elevation because the fuller lip now recreates a bit of an arc. Although useful, this solution is restricted to correction of a minimal problem.

One approach we tried briefly was to directly excise the skin adjacent to the vermilion in a continuous strip. This “upper lip advancement” appeals in theory, because it affords maximal control over the shape of the vermilion border and the contour of the Cupid’s bow. We tried this approach for a time almost 25 years ago and quickly abandoned it because of its nearly 30% contracture rate. Further, when that scar contracts, it is extremely difficult to make an aesthetic surgical revision. In the appropriate patient, we have found it far better to extend a corner mouth lift medially to each apex of the Cupid’s bow and elevate the central lip through a small lip lift.

Lip Lift

We have found an excision under the nostril sill to be a more predictable and controllable solution to a long upper lip. Our founding partner, Harvey Austin, developed the lip lift independently and presented 83 cases in 1986, although others had previously reported it. This lip lift, as we have described it, will shorten the central upper lip and slightly evert it. The procedure was originally designed as a wavy skin excision that leaves the scar in the crease below the nostril sill.

There is no mathematical formula for determining how much to shorten the lip; however, two points are worth making. First, a residual lip length that is shorter than 10 to 12 mm from the nostril sill to the vermilion border will make the lip appear too short. Second, one should overcorrect by a third to allow for postoperative relaxation. Given these caveats, our resections average 5 to 7 mm.

We have performed all of the variations of this excision, and all have utility. Two bear special mention. The first is the one with the central component (*top row, center*). If it takes a certain measure of surgical fortitude to put a scar under the nose, it takes an order of magnitude more to put a scar down the middle of an unscarred upper lip.

Yet this scar heals beautifully, and the subtle narrowing this excision imparts to the upper lip and its enhancement of the Cupid's bow warrant its consideration in the appropriate patient. We have run that central component varying distances down from the labiocolumellar fold, often all the way to the vermilion.

The second variation involves intranasal extensions (*top of page, bottom row, left*). On occasion, a lip lift may give the sense of widening the alar bases. Patients who have real or perceived widening may find their result objectionable for this reason alone. Narrowing the alar verge by simply adding a full-thickness excision intranasally manages this issue.

Outcome and Complications

We have performed more than 1000 lip lifts since 1980, mostly in combination with corner mouth lifts. It has been an extremely reliable procedure with a high rate of patient satisfaction. When problems occur, they usually involve wound healing, asymmetry, or undercorrection. The first two categories are usually handled by revision. We have seen a handful of scars widen beneath the nostril sill. These are usually easily corrected: the tension placed on the skin edges after excising many millimeters of lip skin is now replaced with the slighter tension produced by excising a few millimeters of widened scar. We have seen only a handful of hypertrophic scars (all in Vietnamese patients), and these responded well to injection. Our preferred injection for hypertrophic scars on the face is Kenalog 40 mixed 1:1 with 5-FU. Minor issues with asymmetry often stem from unnoticed preexisting asymmetries and can also be handled with revision.

Although it is straightforward to excise more skin in patients who consider their lips to be undercorrected, overcorrection is more problematic. Of the few we have encountered, most lips have relaxed over time, and the patients have grown comfortable with the result. Time heals many things. Keeping to the excisional parameters outlined earlier and erring on the conservative side in resections should yield excellent results.

Anatomic Variations

Five anatomic variations merit caution:

1. A short upper lip with lack of incisal show
Lengthening the incisors through cosmetic dentistry may be a better solution than further lip shortening.
2. A long upper lip with significant incisal show
Shortening this lip may expose too much incisor.
3. A highly arched lip in which a lip lift could exaggerate the central arch and make the corners appear to turn down
An extended corner lift (discussed later) might be a better solution.
4. A rounded nostril sill that would hide a scar poorly
We have on occasion taken down the nasal spine to make the labiocolumellar angle more acute.
5. A mouth with downturned corners, where a lip lift can further emphasize the downturn
In this instance, it may be better to perform a corner mouth lift concomitantly, or to forego the lip lift altogether.

Downturned Mouth

Around the oral commissure, aging perioral tissues descend and wrap medially, creating a spectrum of anatomic variants of aging over time. The aging mouth can develop an unhappy or even bitter appearance as the lateral lip lengthens, the vermilion rolls inward, marionette grooves form, and the commissure itself eventually descends. Inside the nasolabial folds, indirect approaches to the correction of what we call the *downturned mouth* are remarkably ineffective. Although one might be tempted to elevate this tissue from either a face-lift incision or from the lower lid, we have found any correction to be short lived.

Midface Elevation

Our experience with elevating the midface in an attempt to correct the downturned mouth has been particularly disappointing. Over the years, we have tried different iterations of the procedure (including various combinations of temporal, intraoral, and subciliary incisions). All seem to have some effect on the downturned mouth early after surgery, but as the lift imparted relaxes over time, the ultimate correction is not as pronounced as what might be achieved with a simple corner mouth lift.

Preoperative

1 week postoperatively

3 months postoperatively

This 45-year-old woman came to us unhappy with her angry, tired appearance. She underwent facial rejuvenation that included midface elevation. The downturned mouth corners appear corrected 1 week postoperatively; however, at 3 months those tissues have relaxed significantly and approximate her preoperative appearance.

Corner Mouth Lift

A short upper lip can exaggerate an already downturned mouth. An attempt to solve this problem (in the context of a postcleft whistle deformity) led to the first corner mouth lift by Austin in 1985. His use of a Z-plasty elevated the downturned corners but left rotated tissue below the commissure as an unnatural bulge. Excising this bulge led to its correction and the realization that it was unnecessary. Thus the second iteration of the original corner mouth lift (hereafter referred to simply as a *corner mouth lift*) was developed—a triangular excision of skin designed to rotate the mouth corners cephalad.

To design a corner mouth lift, a mark is first placed at the commissure precisely at the junction of the skin with the vermilion. A line is extended medially along the vermilion border for 10 to 16 mm. If one looks closely, there is often a subtle transition of the three-dimensional curve of the vermilion in this region. If this transition is present, it makes a good place to stop the medial extension.

A second line is then drawn from the commissural mark toward the top of the ear, stopping short of the nasolabial fold.

The ends of the two lines are connected with a third line, the shape of which can be varied to modify the lift of the lateral upper lip vermilion. A slight arc imparted to this third line will evert the lateral lip vermilion more than a straight or concave line will. Most of the third lines have a slight arc to them.

The lift imparted to the corner of the mouth depends on the amount of skin excised. Measured from the commissural mark to the point directly above it on the third line, we have found that 5 to 7 mm of excised skin is our average, 3 to 5 mm gives a small lift, and 7 to 10 mm corrects a more significant downturn.

Wraparound Corner Mouth Lift

One of the disadvantages of the corner mouth lift is the scar. The part of the scar lying along the vermilion border is well concealed, but the portion that lies lateral to the commissure extends onto virgin lip skin and is, to some extent, at the mercy of the vagaries of the healing process. In fact, it is visible in the previous patient's post-operative photo.

To avoid problems encountered with this lateral aspect of the scar, Weston devised the "wraparound" corner mouth lift in 1994. This subtle but important alteration of the corner mouth lift keeps the scar along the vermilion border by wrapping it around the commissure onto the lower lip margin.

Design of the wraparound corner lift begins with the same commissural mark and medially directed line, as described earlier. The second line, however, is directed more vertically than before, toward the lateral canthus rather than toward the tip of the ear.

The third line connects the ends of the other two, as previously described, but now a fourth line is added, running from the commissural mark medially along the lower lip's vermillion border. This fourth line is approximately half as long as its counterpart along the upper lip vermillion, and, with some undermining of the subjacent lip skin, allows the commissural mark to rotate into the apex of the excised triangle of skin.

We have found a deep stitch of 5-0 or 6-0 polyglactin with significant purchase of “perimodiolar” tissue crucial to minimizing the closure tension and ultimate scar, as can be seen in this patient at 3 months postoperatively.

Vermilion Roll-Out

When the commissures require lifting, the wraparound corner mouth lift is an excellent procedure, but it can leave some minor irregularity along the lower lip margin where the excess tissue is worked in. Poindexter realized in 2005 that if the commissure itself does not need lifting (and most do not), a simple excision of skin along the vermilion of the upper lip that stops at the commissure works nicely.

The design of this excision is simpler than that of the other corner mouth lifts. It begins with the same first line (commissural mark to medial endpoint along the vermilion border). The second line then becomes an arc connecting the ends of the first line. This arc ascends sharply from the commissure toward the *medial* canthus, then falls back gradually to meet the medial endpoint of the first line.

Over the past 23 years, we have performed more than 1500 corner mouth lifts and have found it to be one of our most valuable rejuvenative techniques. It has the capacity, more than almost any other single procedure, to alter the overall facial countenance. At its best, it changes sad and angry to almost angelic. Three technical considerations bear mention:

1. The surgeon should err on the conservative side (excisions less than 7 mm). Taking more tissue can lead to secondary effects that become difficult to manage—bulges lateral to the commissure, for example. Keeping resections to this limit also minimizes the problematic depressed scar. Although Juvéderm (Allergan, Santa Barbara, CA) has proved to be a reliable temporary solution, revision has occasionally been necessary.

2. Beware of patients with deep marionette grooves. In these patients, wrapping the corner mouth lift can accentuate these depressions, particularly if the fourth line or lower lip counterincision is not long enough. We have tried undermining and filling the marionette grooves, with varying degrees of success. Their significant presence is one of the indications we still have for a traditional corner mouth lift, and if the grooves are severe enough, they can be improved with a combination of modalities.
3. The skin excision for any version of the corner mouth lift can be extended medially up to the peak of the Cupid's bow without becoming visible. We again caution not to extend the incision to the area between the apexes of the Cupid's bow (as in a full upper lip advancement). At best, this can leave a visible scar with an unnatural, obviously surgical shape. At worst, it can leave a tight band across the central lip. We have found that a better choice is to perform a lip lift to elevate the central lip and a corner mouth lift to elevate the downturned corners.

Nasolabial Region

As an individual ages, the smooth, uncomplicated nasolabial region becomes increasingly complex and difficult to rejuvenate. Initial signs of aging, creases that delineate the fold, serve as tethers for the overlying cheek skin. Tissues thicken and thin around the creases, leading to folds over them and depressions both above (piriform aperture) and below (in the region of the mandibular ligament). How we deal with this area depends on the extent to which the aging process has affected it.

Simple creases in a younger patient often lend themselves to filling alone. We say “often,” because filling creases without somehow exerting a pulling force on them *can lead to unpredictable irregularity in the healing process*. Patients whom it affects—*younger patients who are not quite ready for a face lift, whose adjacent nasolabial skin is otherwise slightly loose and fairly smooth*—are often least able to tolerate this irregularity. These caveats are true for fat injection more than for dermal fillers.

Augmentation of the Nasolabial Folds With Fillers

Nevertheless, filling the creases of the nasolabial fold is a fine technique in many younger patients and in combination with a face lift in older ones. Available substances run the gamut from autologous to alloplastic, from long lasting to short term. As a generalization, it seems to us that the material to be used for any augmentation should as much as possible mirror the tissue into which it is being placed. (The main exception to this rule seems to be the lips, where fat remains our filler of choice.) Fat seems to survive best in fat, dermis/collagen seems to distort skin less than other substances, and silicone or Gore-Tex implants seem to do best placed deep, near the

bone. Thus our preferred filler for directly beneath the nasolabial creases is Juvéderm for short-term correction, and strips of fascia for longer-term correction. One benefit of Juvéderm is that hyaluronidase can quickly and easily “erase” overcorrection. The technique for placement of the latter is straightforward and has been previously described.

Direct Fold Excision

As the aging process continues, the looseness around the nasolabial fold increases until filler is no longer effective. Using it in the volumes necessary is financially cumbersome and can be aesthetically undesirable. Some of these patients consider themselves too young for face lifts. In this group we consider performing direct excision of the nasolabial fold, trading the uniformly thin scar that is barely perceptible at conversational distance for the looseness that is visible from across the room.

Combining this direct excision with a lifting procedure is safe and allows a slightly less aggressive face lift, leaving the patient with a more natural appearance.

Our technique for determining the design follows. Placement of the scars is critical: they should be just medial to the nasolabial furrow and extend no farther than is necessary to excise the laxity.

The variations of our different excisional markings illustrated here are determined by the anatomy of the individual.

In 75% of patients, only the lower nasolabial fold is excised.

In 25%, the inferior aspect of that incision is run laterally (as in the blade of a hockey stick).

Less than 5% of the time, the full length of the nasolabial fold is excised, and on rare occasion folds are excised horizontally.

Key Principles

The nasolabial crease is marked for the length to be excised, trying to leave both ends in depressions so that subtle dog-ears will be masked. The pen is placed over the area of most laxity (usually near the center of the drawn crease line), and the skin is pulled medially without moving the pen.

A dot is placed that will mark the lateralmost border of the excision. This medial pull is repeated a couple of times, with marks as needed to help define the arc of excision before connecting them. In this case, the patient's anatomy suggested we draw the lateral (hockey stick) extension.

The pen is placed back over the crease, and this time the skin of the cheek is pulled laterally, again without moving the pen. There will be less movement in this direction. Again a dot is placed, this time marking the medial extent of the excision. The medial dots are connected to form the outline of the total resection.

Direct Fold Excision With Face Lift

Until a surgeon becomes familiar with the operation, it is prudent to perform the direct excision as a secondary procedure. It is easily done with the use of local anesthesia in an examination room if the nasolabial excess remains problematic after a face lift. However, if on preoperative examination the nasolabial region remains lax while the surgeon simulates a face lift by lateralizing the cheeks with the fingers, we often propose combining the two procedures.

A full-length nasolabial excision is shown. When this is performed in combination with a face lift, the nasolabial fold is excised first. If the nasolabial tissue excision is delayed until after the face lift, the residual swelling associated with the face lift may make it appear that the direct excision is unnecessary. Our experience shows, however, that when the swelling and tightness relax after a few days, the need for direct excision again becomes apparent. Note how the intraoperative tightness has relaxed in the photo on the right, taken 1 week postoperatively.

Over the past 25 years we have performed more than 600 direct excisions of the nasolabial folds. It is difficult to recall patients who have ultimately been dissatisfied during that period, although many are concerned during the first 3 months. Once the redness and firmness fade, however, the scars are almost imperceptible. Even minor irregularities are rare and can almost always be adjusted in the office with the patient under local anesthesia.

Nasal Corner

The upper portion of the nasolabial fold is so rarely excised because it usually shows up as a depression on examination rather than looseness or tissue excess. As people age, the soft tissue overlying the piriform aperture thins until the skin at the corner of the nostril feels like it rests almost on bone. *Filling in this vacant nasal corner is an extraordinarily easy and useful adjunct to almost any rejuvenation.* It can be performed in many different ways.

Filling the Nasal Corner

The simplest way to fill the nasal corner is to inject the area with autologous fat or perhaps fascia. Our preference is for the former, usually injecting from 1 to 2 cc, as was done for this patient. A second method is to insert an equivalent volume of SMAS or mastoid fascia into that region through a stab incision usually made just inside the nostril verge. Through that incision a Joseph elevator is used to create a small pocket into which the tissue is inserted. An alloplastic option is to place a small triangle of silicone carved from either a cheek or chin implant along the bone from an incision in the upper buccal sulcus or from the nostril verge. Brink implants (Implantech, Ventura, CA), with or without the connection overlying the nasal spine, are quite useful in this regard.

Resurfacing Procedures

Resurfacing the perioral area is both old and new. Modalities such as dermabrasion, peels, and lasers have been in use long enough to be well understood by most experienced surgeons. However, integrating resurfacing into a comprehensive plan to rejuvenate a harmonious face is something with which we continue to struggle.

Young faces are not wrinkled and are evenly pigmented. Nothing symbolizes an old face more than wrinkles. Rhytids vary from fine to coarse and can either be confined to one area (initially perioral or periocular) or can be distributed more globally. Although often only the perioral area is resurfaced with facial rejuvenation, in a globally wrinkled aged face, consideration must be given to resurfacing the entire face. In the end, the quality of skin in all areas of the face should be consistent.

For fine wrinkling confined to the perioral region, we primarily rely on dermabrasion and the tunable erbium laser (Sciton, Palo Alto, CA). For the former, painting the skin with a light coat of methylene blue and removing it with a coarse diamond fraise (cleaning it frequently with a toothbrush dipped in peroxide to prevent clogging the fraise's interstices) provides a nice margin of safety.

As the rhytids become coarser, dermabrasion and the Sciton laser remain our mainstays. In addition, we almost always undercut the deeper rhytids with an 18-gauge needle and fill that undercut with a drop of autologous fat.

The settings for the Sciton laser vary, but we have found a single pass with 40 microns of ablation will almost universally induce a light peel. As the skin peels, much of the solar dyschromia comes off with it, and at this fluence, this laser appears safe for undermined skin. This becomes important in integrating any deeper central laser treatment (perioral, nasal, and forehead) in one stage with a face lift. By going deeper in the central (not undermined) regions of the face with the laser tuned for coagulation, we are able to erase most fine to moderate wrinkling and still blend the color change in that central area with the rest of the face in one session.

This 64-year-old patient demonstrates this principle. Of note here is the use of fat grafting as an adjunctive modality for treating wrinkles. When the wrinkles are fine and radially oriented, adding fat beneath the vermilion will sometimes stretch the vermilion border enough to obviate the need for resurfacing. Certainly, it is a good adjunct procedure. Botulinum toxin, 2 to 4 units placed intermittently along the upper lip, is also useful in the short term and can be done adjunctively with fat injections.

Deeper resurfacing always runs the risk of hypopigmentation, and every surgeon must perform his or her own calculus. Recently, ours has erred on the side of leaving rhytids rather than risking an uncorrectable skin discoloration. One can always perform a secondary wrinkle procedure.

We reserve the use of phenol for the deepest rhytids, which in our practice are relatively rare. Deep resurfacing poses the problem of combining a very powerful resurfacing modality with lifting procedures in one stage. We have used all manner of lasers (CO_2 , tunable, regular erbium, fractionated) and 35% trichloroacetic acid during face lifts and have used them to resurface flaps at the same time. We have yet to resurface an undermined flap with phenol and cannot envision a situation in which we would attempt it. We have therefore used phenol centrally (brow, nose, and mouth) and combined it with other resurfacing agents on the flap, or we simply stage the lifting procedures with a full-face phenol peel.

This middle-aged woman underwent a phenol peel to resurface her perioral region. There is persistent redness following the procedure, which is typical of the prolonged recovery from the deeper peels.

Nasolabial Variants and the Marionette Groove

Folds of tissue around the nasolabial crease can be massed primarily either medial or lateral to the crease itself, the former commonly known as the *marionette groove*. The clinical implication of this distinction is that lateral tissue can be expected to respond better to all modalities (face lifts, skin-tightening resurfacing, and direct excisions) than will medial tissue.

This patient demonstrates both variants; she underwent a face lift with deep central Sciton laser resurfacing and fat grafting. Three months postoperatively, it can be seen that the modalities had less effect on the patient's right side in effacing the marionette groove.

Temporary correction of the marionette groove can be achieved nicely with Juvéderm (less than 1 cc) and/or *botulinum* toxin (4 to 6 units) placed into the depressor anguli oris (identified by asking the patient to exaggerate the marionette groove while the surgeon palpates the area for muscle contraction).

More permanent correction is often best achieved by combining direct excision (or skin tightening laser) of any lateral nasolabial excess with subcision of the marionette groove. For this we use a 14-gauge needle and then inject fat. A horizontal mattress suture of 6-0 Prolene can be used to elevate the subcised tissue during the early phase of healing. Four units of botulinum toxin may be useful during healing.

The Vermilion: Restoring Shape and Volume

The lips thin and roll inward as we age, and the vermilion can virtually disappear, making one look old and bitter. Although the lip lift and corner mouth lift both expose more vermilion, the primary goals of those techniques are to correct a long upper lip and drooping mouth corner, not to correct thin lips or contour the lower lip vermilion. Restoring volume to the lips not only helps re-create the plumpness of youth but also helps to subtly rejuvenate the complex anatomy around the commissures. Advancing the lower lip vermilion is also indicated on occasion, usually in the older patient or aged face.

Fat Grafts

For moderately thin lips, we prefer fat grafting. Although we have found the lips to be one of the places on the face with the most variable “take,” grafting fat remains a workhorse, because of its low cost, availability, and ease of use. The technique can be as accurate as threading tissue grafts; the survival rate in our hands varies from 0% to 70%. We have begun freezing fat for later injection with the patient under local anesthesia. Although cell culture techniques suggest that these cells do not survive without a special culture medium, we suspect additional volume may be achieved through the scarring process.

Alloplastic Fillers

Alloplastic materials are a nice fallback should fat resorb completely or be found objectionable by the patient. Hyaluronic acids have been our favorites. Collagen has a long history, and its strengths and weaknesses are well known. Autologen was a nice idea but was financially impractical and is of historical interest. AlloDerm may have utility, but it is expensive, and we have no experience with its use in the lips. We have found Radiance disastrously lumpy. We have essentially abandoned implanting Gore-Tex in the lips, because too many unnatural results warranted its removal.

Lip Advancement

In aged lips, when the *lower* lip is very thin or has rolled inward significantly, tissue grafts for volume may be inadequate, and lip advancement should be considered. As mentioned earlier, upper lip vermillion advancements done by excision of a continuous strip of upper lip skin, including the prolabial portion between the peaks of the Cupid’s bow, are risky, because they can sometimes contract and flatten the Cupid’s bow. Even the best of scars in this area are fairly noticeable.

As discussed earlier, a better solution is to extend the corner mouth lift up to the ipsilateral peak of the Cupid’s bow and perform a small central lip lift, as was done for this patient. (Fat was also grafted to the lips.)

The lower lip architecture is less complex than that of the upper lip, and lower lip advancement is a reliable way to expose more lower lip vermilion. A strip of subjacent skin is excised from corner to corner, twice as wide as the amount of advancement desired. The scar lands at the vermilion border and is usually imperceptible, even from inches away. When combined with the corner mouth lift, a small gap should be left between the incisions at the commissure to prevent the possibility of scar contraction.

Mucosal Advancement Flaps

Mucosal advancement flaps can also be used to increase mucosal volume and change the shape of the vermilion. We now rarely use them because they lengthen the upper lip, and patients complain about how the mucosal scars feel. We prefer the other procedures described earlier.

Ancillary Procedures

Correction of a Witch's Chin

We have tried many ways to correct a ptotic chin pad, or *witch's chin*, and have found the following technique to be a straightforward and reliable way to go about it.

Through a submental incision, the fat pad of the chin is isolated on a superior pedicle by separating it from the skin above and periosteum below. This dissection must be generous enough, particularly laterally, to allow for the free rotation of the fat flap up under itself. Attaching a “leading” stitch to the apex of the flap and directing that stitch along the periosteum and out the labiomental fold easily accomplishes that rotation. Taping the stitch in place fixes the flap.

This 62-year-old woman was unhappy with her aging face but was particularly focused on her ptotic witch’s chin. She underwent a facial rejuvenation that included correction of her ptotic chin pad by rotation of the superiorly based fat flap. Results are shown at 4 months postoperatively. She is delighted with the improvement.

Reshaping the Philtral Columns

A smooth, round, simian upper lip is simply not youthful. We have discussed ways of recreating vermilion contour (lip lifts and fat grafts) but have only alluded to recreating the subtle anatomy around the philtral columns; a lip lift with a central component will often suggest columns by creating a philtral dimple and, if extended far enough, a “pouty” apex to the Cupid’s bow.

Hills are often hills because they are next to valleys. Creating a philtral dimple is sometimes enough to rejuvenate the philtral region. This can be accomplished by the lip lift with a central component, or by simply undermining the lip lift and taking a partial-thickness “scoop” of orbicularis oris muscle. The resultant cleft mimics the philtral dimple.

The actual creation of philtral columns is a bit more difficult. We have used fat grafting without great success. Fat seems to live poorly in this tight, mobile area. Juvéderm works well, but its effects are relatively short lived. Fascial strips seem to be a good option and are currently our preferred choice when the patient desires a more permanent solution. They are placed by attaching a leading stitch onto the end of the strip, then into a 14-gauge needle that is placed under the skin in the desired location of the philtral column. Austin had found it useful to wrap these strips in polyglactin.

Concluding Thoughts

We have found that surgical rejuvenation of the aging mouth often requires a more direct approach than most plastic surgeons are routinely comfortable with. Our usual trade-off of scar for shape takes on new meaning when the scar might lie along the vermilion border, on the nostril sill, or along what was a nasolabial crease. Nevertheless, in more than 80 combined years of practice and in more than 3000 patients, we have found that trade-off not only worthwhile but a wonderful adjunctive solution to difficult rejuvenative problems.

Clinical Caveats

At least 10 to 12 mm of upper lip should be left after a lip lift.

It is better on the conservative side for corner lifts; lip lift excisions should be less than 7 mm.

If the commissure itself is in good position and does not need lifting, a vermilion roll-out should be considered.

The surgeon should beware of a patient with deep marionette grooves. In these patients, wrapping the corner mouth lift can accentuate these depressions, particularly if the fourth line or lower lip counterincision is not made long enough.

Caution should be exercised when combining a lip lift with an open rhinoplasty.

Annotated Bibliography

Austin H. The lip lift. *Plast Reconstr Surg* 77:990-994, 1986.

The author focuses on a seldom-considered sign of aging—lengthening of the upper lip. He presents his technique for correction: excision of a wavy ellipse of lip skin and hiding the scar up under the nose. A vertical midline component may be added. The scars are minimal, and the results have been excellent in 83 patients.

Austin H, Weston G. Rejuvenation of the aging mouth. *Clin Plast Surg* 19:511-524, 1992.

By viewing the face as a series of three concentric rings, we can successfully rejuvenate the outer ring with the usual face lift, blepharoplasty, and brow lift. However, insufficient attention has been paid to the middle and inner rings. This article discusses the technique for mouth rejuvenation in both of these rings.

CHAPTER 52

Refinements in Otoplasty Techniques

BRUCE S. BAUER, NETA ADLER

Despite recognized standards of idealized facial proportions and anthropometric measurements for each facial feature, the sought-after “look” of the moment tends to change, depending on which new fashion model or celebrity is hot, or which individuals are currently revered in today’s media. Strangely, when wishing to depict an oddball character, a less intelligent individual, or a “funny-looking kid,” the media often portray individuals with large, prominent, or oddly shaped ears. Regardless of what we may later learn about these characters, we initially assign a level of low intellect or immaturity to them. The fact remains that without calipers or other instruments of measure, and without memorizing a set of standards, we visually recognize when facial features appear to be in balance, and few if any features elicit such negative responses as ears that are prominent, overly large, or misshapen. Like it or not, we tend to attribute these negative traits to these unfortunate individuals.

The literature in plastic surgery and otolaryngology abounds with approaches to correct these deformities, many described as the “definitive procedure.” Yet the failure to properly analyze each deformity and modify the technique to fit the specific features of each ear is likely to lead to an unfavorable outcome. Although the vast majority of otoplasty patients are extremely pleased with the outcome of their surgeries, there are few patients more distraught than those whose previously attention-grabbing ears are now less prominent—but just as unsightly.

In this chapter we will outline the evolution of our current technique for correction of the prominent ear. We will demonstrate how the technique has been modified to make it flexible enough to correct a wide variety of deformities, from simple ear prominence to an accompanying deformation of the helical rim, excessive prominence of the lobule, and moderate degrees of constriction. To master the technique, surgeons must understand how to properly balance and subtly position the varied ear contours to obtain an outcome that “looks right” and that does not immediately tell the observer that the ears have been operated on. Although the final ear position and shape are critical, the exact measurements are not.

Indications and Contraindications

Many of the patients presenting for otoplasty are easy to spot in a crowded waiting room, but not every person with large, prominent ears wants to change his or her appearance, and many, even if teased in childhood, have become comfortable with their appearance. That being said, experience has demonstrated that many of the parents bringing their children in for correction of prominent ears are strongly motivated by the desire to spare their child the embarrassment and teasing that they themselves endured. More than a few have subsequently elected to undergo otoplasty after their child has had surgery. In these cases the satisfaction rate and feelings of relief are a constant feature of their recovery.

These issues come into play in deciding the appropriate timing for the surgery, and whether the decision should be made based on the parents' concerns or whether the surgery should be postponed until the child expresses concern. Such a decision needs to be made case by case, but by the time children approach 5 years of age, they may well have been teased, even if the teasing has not started to affect the way they feel about themselves. Once the discussion is initiated, the child will express willingness to go through the surgery to avoid this teasing.

The growth patterns of the ear also factor into the timing of surgery. According to Adamson et al, the external ear reaches 85% of its adult size by the time a child is 3 years of age. Growth continues until adulthood, but little change in width or distance from the scalp occurs after 10 years of age, and for all practical purposes the normal ear is almost fully developed by 6 years of age. Farkas reported slightly different data, with the ear reaching 85% of full size by 8 years of age, 90% by 9 years, and 95% by 14 years.

Although it is quite possible to correct a protruding ear before 5 years of age with no effect on the growth of the ear, it has been our experience that children younger than 5 years of age are rarely perceptive enough about their appearance, or comments made about them, to feel that correction is urgent. Experience has demonstrated that young children may have significant difficulty cooperating with postoperative routines, such as dressings and limitations on activity. The ear cartilage at ages younger than 5 years may be softer and more pliable, and thus the risk is greater that some degree of protrusion will recur. Taken together, with very rare exceptions, age 5 is the low end of our patient spectrum.

More subtle cases of ear prominence, distortion of ear shape, or ear asymmetry may not spark the desire for correction until a child is older, more concerned about overall appearance, or eager to adopt a different style and wear his or her hair back or cut short. In each case, the ear or ears that may have been kept well hidden are now exposed for all to see.

There are very few contraindications to otoplasty. In the pediatric population, surgery is appropriate and extremely well tolerated if the child does not strongly resist the idea of surgery. If a younger child begins to act out or becomes excessively worried about going to the doctor for a preoperative discussion or going to the hospital, it is best to delay the surgery until the child requests the procedure. Another contraindication is a history of chronic ear infection and ear drainage that has not been thoroughly investigated and corrected. It is not uncommon for children to have previously undergone myringotomy and placement of a pressure equalization tube. If there is no active infection or significant drainage, otoplasty can be performed safely.

At the other end of the age spectrum, adults seeking changes in ear shape, size, or prominence must, as with any aesthetic surgery candidates, be able to express their

reasons for seeking a change at this stage and demonstrate realistic expectations of what the change will mean for them. Careful case selection is critical, and never more important than when the deformity is a minimal or subtle one. Although beyond the scope of this chapter, the same is especially true in patients who have previously undergone one otoplasty and are dissatisfied with the outcome.

Pertinent Anatomy

Anatomy of Ear Prominence

Although the majority of otoplasty techniques have historically concentrated on the effaced antihelical fold as the main cause of ear prominence, failure to fully appreciate all the elements distorting the ear position and shape is a recipe for an unfavorable outcome. Experience has revealed that the vast majority of prominent ears demonstrate some degree of conchal hypertrophy, and the concha may be the cornerstone to the treatment of the prominent ear.

Causes of Ear Prominence

Correct analysis of each deformity is the most important step in otoplasty. Ear prominence results from one or more of the following features: (1) effacement or a deficient antihelical fold, (2) conchal hypertrophy or abnormalities in conchal shape, (3) deformity of the underlying skeletal anatomy, and (4) macrotia, or generalized overgrowth of the ear. The first two of these features are accentuated when seen in combination with the decreased radius of curve of the helical rim in a constricted ear. We will look at each of these elements separately.

Antihelical Fold

Effacement or deficiency of the antihelical fold ranks foremost in most discussions of the prominent ear. This deformity presents as a spectrum from a totally indistinguishable antihelix, with a confluent concavity from antihelix to scapha and the helical rim projected outward and forward, to loss of definition of only the superior antihelix with prominence of the upper pole of the ear.

Conchal Size and Shape

Although less attention has been given to the importance of the concha in overall shape and projection of the ear, it makes sense in considering the three-tiered configuration of the auricular cartilage framework that because the more delicate antihelix and helical complex are mounted on the sturdier concha, changes in conchal size and shape will profoundly influence the overlying tiers. In our experience, it is rare to see ear prominence that does not have some conchal element.

There appear to be three ways in which the concha affects the prominence of the ear: (1) overall enlargement of the concha, which projects the ear away from the mastoid surface, (2) an extension of the helical crus across the concha, which creates a firm “cartilage bar” that pushes the ear outward, and (3) the effect of the angulation of the cartilage at the junction between the cavum concha and the sweep of cartilage up to the antitragal prominence, which affects the position and prominence of the lobule and lower third of the ear. The first of these is well recognized. Little attention has been drawn to the second, but once seen, it is easy to understand. The third element, once recognized, leads to an understanding of the approach to the isolated lower pole and lobule prominence.

Conchal shape, although not the only cause of prominence of the lobule, appears to play a key role. As the cartilage angle between the concha cavum and antitragus becomes more acute (that is, as the antitragus tips closer toward the concha), this supporting structure projects the lower third of the ear and lobule outward. We think that this feature has a greater influence on lobule position than the commonly described helical tail does.

Anatomy of the Underlying Skeleton

Little attention has been drawn to the affect of the underlying skeleton on ear prominence, but it should be recognized and taken into account in planning correction of a prominent ear. The external ear is mounted on the bony base of the underlying temporal bone. Anomalies in skeletal shape and skeletal asymmetries can affect one or both ears. Perhaps the most recognizable example of this relationship is the change in ear position and projection associated with positional, nonsynostotic plagiocephaly. With the parallelogram deformation of the cranial vault, the ear on the side of occipital plagiocephaly is projected forward and is often more prominent. In more subtle cases of this deformity, the ear prominence may become more evident when

the individual is older, with ears that are asymmetrically positioned, and residual occipital flattening and mild facial asymmetry may not be readily apparent on first view. This effect of head shape on ear position is clear when viewing illustrations of Ely's description of his otoplasty technique in 1881.

A less subtle example of the influence of the skeleton on ear position is the effect of deficient temporal bone and medial positioning of the temporomandibular joint in hemifacial microsomia. In more severely affected patients without microtia, the normal ear may seem to be "sheered off the head," with the upper half of the ear projecting outward and the lower half canted medially toward the hypoplastic face. An additional example with some similarities is the small group of patients whose general craniofacial shape includes a relatively broad head, with a narrow face and mandible. Seen from the frontal view, there is a triangular configuration to the head and face. This slope from head to face may project the upper ear outward, creating ear prominence, but showing otherwise normal and proportional ear features.

Macrotia

There are wide variations in ear size and a broad spectrum of "normal," but some patients have overall enlargement of the ear, out of proportion to the other facial features. This may occur as a result of congenital overgrowth in isolation, or in combination with hemihypertrophy of the face. It may also occur as a result of a disease process, such as neurofibromatosis, or a vascular anomaly. The ear, while enlarged, may be normal in shape, or show elements of the above-mentioned features. Each of these anomalies is relatively rare. Less rare, and not true macrotia, is an isolated congenital enlargement of the lobule, with the lower third of the ear projecting outward from the face.

Preoperative Assessment

In the majority of cases, if the patient is a child at an appropriate age to undergo a procedure, the preoperative assessment is completed with the initial evaluation and one subsequent preoperative visit (usually within the week before surgery). For children too young for surgery, or not presently concerned with the deformity, a return visit is planned for the appropriate age. For an adult patient, particularly one requesting a secondary procedure, the surgeon may elect to meet an additional time to ensure that the patient's expectations are appropriate and can be fulfilled. All patients require routine history-taking and a physical examination (plus a laboratory workup in adults) to be completed by the primary physician. Photographs are taken preoperatively and reviewed to ensure that all appropriate views are documented.

The specifics of the deformity are discussed with the patient or family, taking care to point out any asymmetries that may exist between the two ears. The surgical pro-

cedure is discussed in detail, including a review of the options for anesthesia (a general anesthetic is used in the majority of pediatric cases; possibly a local anesthetic with or without sedation in minor cases or in adults), discussion of incisions, dressings, and postoperative care. Such risks as infection, chondritis, and hematoma are discussed, as well as their implications and treatment. The surgeon also discusses the fact that there may be minor asymmetry or a partial recurrence in younger patients that can be corrected through a minor revisional procedure with a local anesthetic when the child is ready and comfortable with this.

In most cases, and particularly in children, it is helpful to review photographs of a series of otoplasty cases illustrating a variety of prominent ear deformities. With some of the more atypical deformities of the helical rim or with a constricted ear, this will help to clarify the potential limitations of the surgery while still demonstrating its benefits.

Preoperative Planning

Proper assessment of the patient's deformity is the key element of preoperative planning. Our current approach to correction of the prominent ear evolved from the Stark-Saunders technique, which combined posterior thinning (dermabrasion) of the proposed antihelical fold and suture fixation; our technique emphasizes chondrocutaneous conchal resection as the cornerstone of correction of the prominent ear, combined with posterior suture shaping and fixation of the antihelical fold. Our current approach totally avoids any thinning or potential irregularities in the antihelix seen with many of the cartilage-scoring techniques, while still minimizing the risk of recurrence that may be seen with suture techniques alone. The integrity of the antihelical cartilage is maintained because the perichondrium overlying both surfaces of the antihelix is left undisturbed, yet the cartilage spring is diminished as a result of the "break" at the conchal level.

This evolution in our approach followed assessment of our own postoperative results as well as critical evaluation of a reasonably large series of patients seeking revision otoplasty. In the latter group, most demonstrated an overaccentuation of the antihelical fold and failure to recognize conchal hypertrophy as the underlying cause of the initial ear prominence. Addressing conchal hypertrophy in these patients, alone or in conjunction with ancillary techniques, has produced consistent and reproducible outcomes that are satisfactory to both the patient and surgeon.

The goals of otoplasty should be to (1) correct the protrusion, (2) correct the prominently visible helix and antihelix while leaving a visible helical rim (3) create a smooth antihelical fold, (4) avoid disturbance of the postauricular sulcus, and (5) avoid a "plastered down" or "pinned back" look. To achieve these goals, each deformity must be critically evaluated and the technique modified to correct subtle differences in the two sides.

Whereas emphasis had previously been placed on the importance of correcting the antihelical effacement, this approach emphasizes the concha's role in the prominent ear. This results in a treatment plan that readily achieves each of the above goals while guaranteeing that a sharp, irregular antihelix and pinned-back look will be avoided. The technique is also readily modified to suit the correction needs of a whole host of unusual or atypical deformities.

With the exception of the rare cases in which there is no visible conchal component to the deformity, the procedure begins with an anterior conchal incision, and excision of a crescent of cartilage with a smaller skin component. For a lesser degree of cartilage resection, no skin may be excised. Although minor degrees of conchal prominence can be handled by creation of a new antihelical fold or by setback with conchal mastoid suture, most patients with conchal hypertrophy require cartilage excision. The choice of an anterior or a posterior approach to cartilage excision is one of personal preference. In our opinion there is considerably more control with the anterior approach, and in cases with wider resection of 1 cm or more, the extra skin left from the use of a posterior approach may not shrink down enough. The fold created in the conchal floor can be much more noticeable than a finer anterior conchal scar that is rarely visible by 1 year after otoplasty.

After repair of the concha, the surgeon turns attention to the postauricular surface, where skin excision and exposure of the posterior perichondrium over the scapha, helical sulcus, and helical tail are followed by suture placement. Sutures are tied to correct the prominence, and closure of the inferior incision sets the shape and correction of the lobule. Next the surgeon performs adjunctive procedures, such as correction of helical rim deformities, excessive prominence of the antitragus, and additional reduction of lobule size. Corrections of adhesion or defects of the helical rim may make use of the resected conchal cartilage as a graft.

Operative Technique

52-1 Otoplasty

Although we will make every effort in this section to describe the nuances of each step, the indications and benefits of each maneuver will become readily evident as one gains more experience with the procedure and better appreciates the flexibility inherent in this approach. With rare exceptions, which will be noted, the techniques used are similar for children and adults.

General anesthesia is induced with a reverse airway endotracheal tube, or intravenous sedation is used. The face and both ears are sterilized with a green soap solution and draped with a standard head drape. Stray hairs are secured with Tegoderm or another clear sterile drape. A solution of 0.5% lidocaine with 1:200,000 epinephrine is infiltrated into the anterior and posterior surfaces of both ears. Bilat-

eral great auricular nerve blocks with 0.25% bupivacaine are also injected for postoperative analgesia. A broad-spectrum antibiotic is given intravenously after placement of the IV line.

The procedure typically begins on the more prominent side and starts with the incision on the anterior surface of the concha. The incision is placed at the junction of the posterior conchal wall and “floor” of the concha. It begins in the cymba concha and continues along the cavum concha to a point below the antitragus, but not as far as the external auditory meatus.

This incision is deeper in the concha than the incision described by Elliott. Placing the incision too high in the concha will decrease control of the antihelical fold, allowing the cut edge adjacent to the antihelix to spring forward when the antihelix is shaped. The incision is carried through both the anterior skin and conchal cartilage, stopping shy of the posterior conchal skin.

Sharp dissection in the loose areolar plane behind the concha (not in the subperichondrial plane) frees soft tissue and skin from the posterior surface of the conchal bowl.

A gentle setback of the antihelix with finger pressure will accurately estimate the degree of conchal hypertrophy and the amount of cartilage and skin resection needed to create an aesthetically pleasing position for the ear.

Usually a crescent-shaped chondrocutaneous segment is excised. To ensure a tension-free closure, more cartilage is typically resected than skin, particularly along the inferior concha deep to the antitragus (where excessive resection would tend to pull the antitragus upward and increase prominence of the lower pole of the ear and lobe).

The edges of the conchal cartilage are then approximated with three or four interrupted 5-0 clear nylon sutures. How the most inferior suture is placed, at the junction of cavum concha and antitragus, will adjust the angle between these landmarks and strongly influence the cartilage support to the lobule. A slight overlapping of cartilage (antitragal segment over conchal segment) will tip the lobule posteriorly.

Once the cartilage is repaired, the anterior skin is closed with a combination of 5-0 chromic gut, with horizontal mattress sutures, followed by a running 6-0 mild (fast-absorbing) chromic gut. With these maneuvers completed, the helical rim and ear may at first seem more prominent, but gentle pressure applied to the antihelix will demonstrate a relaxing of the tension needed to bend the antihelix back to its desired correction.

Correction of the effaced antihelix and prominence of the lobule first begins with a retroauricular “squid”-shaped skin excision down to the perichondrium. This squid-shaped excision (which, in essence, is the typical dumbbell-shaped ellipse with the inferior end widened to a diamond shape) is designed to allow access to the posterior surface of the scapha and helical sulcus for suture placement and to assist in correction of the lower pole prominence. The diamond-shaped inferior extension of the “squid” is positioned with its maximal width at the point of maximal lobule prominence. When designing the squid-shaped excision, failure to taper the skin excision in its midportion may result in a postoperative “telephone-ear” deformity in which the upper ear and lobule protrude, resulting in an ear shaped somewhat like the hand-set of a telephone. Exposure of the posterior surface of the conchal bowl and scapha is achieved without dissection of any perichondrium off the cartilage. Preserving the perichondrium is essential to lessen the possibility of subsequent sutures pulling through the cartilage. As the dissection proceeds to expose the posterior surface of the cartilage, care is taken to identify and free the helical tail. The latter is seen as a duplication of cartilage extending inferiorly from the middle to the lower third of the helical rim. This dissection must not free the cartilage of the tail from the skin overlying its anterior surface, because this would diminish the effectiveness of correcting the prominence of the lobule. The final dissection proceeds onto the mastoid surface, freeing the soft tissues sufficiently to ensure that later sutures can be securely placed into the mastoid fascia. Bipolar cautery is used throughout to ensure hemostasis.

Before placing sutures that will further correct the ear prominence, the surgeon gently puts pressure on the helical rim and antihelix to again demonstrate that the spring (resistance of the cartilage to further shaping of the antihelix) is significantly decreased, and now the reshaping can be accomplished without any sharpening of the antihelix. Surgeons must recognize this key point of this otoplasty technique, because even a limited amount of conchal resection will still result in this lessened spring and increased ease of shaping the antihelix. With the current exposure of the posterior surface of the concha, if additional sutures are needed to complete an accurate closure of the conchal defect, they can be placed now before the key posterior shaping sutures are done.

Two or three 4-0 clear nylon sutures are placed from the scaphal cartilage and helical sulcus cartilage to the mastoid fascia to correct prominence of the upper and middle third of the ear. The third superiormost suture may be placed from the region of the triangular fossa to the temporal fascia. The proper placement of these permanent sutures is confirmed by applying pressure to the desired points on the anterior surface of the ear with a straight Keith needle, then passing the point of the needle through the selected spot so it can be visualized on the posterior surface of the cartilage.

The nylon suture is then placed at each specific point without the need of tattooing the cartilage. As the suture is placed, the Keith needle is withdrawn. The sutures are then passed through mastoid or temporal fascia.

Once all sutures are placed, beginning with the scaphal suture, they are tied to the proper tension to create a smooth antihelical fold. Before cutting each suture, the surgeon uses a forceps to grasp the knot and slide it down against the mastoid surface to minimize any risk of later extrusion of sutures. As these sutures are tied, care should be taken to observe the relationship of the reshaped antihelix and the helical rim to ensure that the helical rim remains visible from the frontal view. A triangular fossa-to-temporal fascia suture is required only if there is a need to pull the helical root closer to the head. This is best determined by looking at the superior helical rim from the anterior view to see if there is a gentle slope downward from the apex of the helical rim toward the helical crus. If the rim bulges forward after the superior suture has been placed from scapha to mastoid, then this additional suture is required.

In adult patients, in whom there may be less flexibility in the cartilage of the antihelix, one or two additional sutures may be required to shape and round the antihelix. These sutures are placed from scapha to the cut edge of the concha, deep to the inferior crus, and from the helical sulcus to the cut edge of the concha at right angles to the antihelix. These sutures are placed before the ones described above to

“preshape” the antihelix before further correction of the prominence. This maneuver is in lieu of other otoabrasion techniques that, even if done carefully, may still result in irregularities on the anterior surface of the antihelix.

Once the upper and midauricular prominence is corrected the lobule position is addressed with closure of the posterior squid-shaped defect using 5-0 chromic gut. With the diamond-shaped inferior portion of the squid designed as described previously, the appropriate contour, shape, and projection of the lobule are produced by varying the initial suture position, with A' (the point of the diamond at the point of maximal lobule prominence) sutured to either A, B, or C (most frequently A' to A rather than A' to B). Once this initial suture is placed, the closure is completed with a running 5-0 chromic suture. Correction of the more prominent side first allows a symmetrical setback by providing a guide for placement of the sutures that will define the antihelix and lobule prominence.

The most common adjunctive procedures include reduction of prominence of the antitragus and correction of irregularities in the helical rim in the area of Darwin's tubercle. Each of these procedures is accomplished through a small incision parallel to the border of the prominence (within the concha for the antitragus, lateral to

the helical rim for helical rim adjustment), followed by direct exposure and resection of the excess cartilage. Closure is done with an interrupted and running 6-0 mild chromic suture. (Additional procedures to treat major deformities of the helical rim, or reduction of excessively large lobule, are reviewed later, with specific examples.) Small degrees of lobule enlargement can be addressed with a small wedge resection within the lobule, whereas larger resections are best placed at the lobule-midthird (helix-antihelix) junction, where the splice can be stair-stepped at the splice point. These procedures are the exception, not the rule.

Macrotia

Cases of true macrotia require reduction of the overall ear size in addition to correction of ear prominence. In general, reducing the vertical height of the ear is most easily accomplished with an excision at the junction of the middle and lower thirds of the ear in conjunction with helical rim advancement using a posteriorly based chondrocutaneous flap. The excess skin and cartilage are excised from the scaphal region, the rim is advanced along, and additional skin and cartilage are excised just inferior to the helical tail. This approach affords an excellent view for either further development of the helical fold or additional conchal reduction.

Dressings and Postoperative Care

The ears are dressed with bacitracin ointment, Xeroform gauze, and fluff dressings secured with a stretch net head wrap. The dressing is left undisturbed for 6 or 7 days postoperatively and then removed. Broad-spectrum antibiotic coverage is continued for 4 or 5 days postoperatively. After the dressing is removed, the patient wears a

stretch terry sport headband for an additional 2 weeks, at night only. Physical activity must be minimized for 3 weeks after surgery. After the dressing is removed, the patient's hair should be washed daily with mild shampoo and the ears cleansed gently. This is continued until the sutures have dissolved. Patients are typically reevaluated at 6 and 12 months postoperatively.

Outcomes

Despite the preponderance of techniques describing accentuation of the antihelical fold as the key component of correction of the prominent ear, our experience has led to the conclusion that the prominent ear has many and varied etiologic factors, but the common denominator is hypertrophy of the concha. The degree of conchal hypertrophy does not need to be great to have a positive impact when employing chondrocutaneous resection as the cornerstone of the otoplasty technique. Recognizing this fact is imperative, but at present it is underappreciated. Even with limited resection and resuturing of the cut concha, the antihelix yields to the posterior placement of sutures with a soft, smooth, rounded shape, unmarred by any sharp irregular surfaces. Despite concerns expressed by some authors, and criticism of the anterior approach to the concha as a potential source of a keloid scar, we have not seen unsightly scarring in any of these cases, nor in a much larger series of conchal donor sites for composite grafts used for ear reconstruction. This approach can readily be adapted to the treatment of less common deformities and can be applied to correction of deformities seen in group I and II constriction (where the deformity is bilateral and significant increase in ear height is not required).

Although a small number of patients will have minor asymmetries in the upper pole correction or in lobule shape or prominence, the adjunctive procedures mentioned earlier are now applied more routinely at the initial procedure to avoid these issues. To date, all revisional procedures, even in younger children, have been done in a single procedure with local anesthetic in the office setting.

Results

The versatility of this approach is illustrated in the following patient examples, ranging from typical ear prominence to varied deformities of the helical rim and moderate constriction of the ear.

This 14-year-old girl's ear prominence resulted from a mild degree of underdevelopment of the antihelical fold, with conchal hypertrophy playing a greater role in the prominence, particularly on the more prominent left side. She is seen 9 months postoperatively. The smooth contour of the antihelix is apparent in the lateral views.

The antihelical folds were barely visible in this 13-year-old with prominent ears, and there was significant conchal hypertrophy. The superior antihelical fold was barely developed, and the prominence was greater on the left side. The postoperative results at 1 year after correction demonstrate excellent symmetry, clearly visible helical rims on frontal and posterior views, and smooth antihelical folds on the lateral view.

This 37-year-old woman had relatively symmetrical bilateral ear prominence, with a mild degree of conchal hypertrophy, a relatively well-developed lower segment of the antihelical fold, and primarily upper pole prominence. In the preoperative views, an additional deformity of the helical rim can be seen on the right side in the region of Darwin's tubercle. Our surgical approach was similar to the technique described

earlier, with a small conchal reduction followed by posterior placement of sutures to correct the upper pole deformity. The helical rim deformity was approached through an incision paralleling the helical rim, and the cartilage of the rim was exposed. The cartilage was found to be relatively normal, with the deformity primarily resulting from an excess of skin and subcutaneous fat in the region. The latter was resected, correcting the deformity. The patient is shown 13 months postoperatively. The subtle degree of conchal reduction allowed correction of prominence without sharpening the lower and middle region of the antihelix. The superior antihelical fold is better defined, and the helical rim deformity is corrected.

This 6-year-old boy with “skip hemihypertrophy” had enlargement of the structures on the left side of his face and right side of his trunk and extremities. Although both ears were prominent, as seen on frontal and posterior views, the left concha was larger, the antihelical fold less defined, and the overall ear size was larger. Correction of the prominence involved bilateral conchal reduction combined with reduction of the size of the left ear. This was accomplished with additional resection of a segment of the scapha through an incision parallel to and within the helical

curve, which released the helical rim to allow advancement and resplicing at the junction with the lobule.

The 1-year postoperative frontal and posterior views show excellent symmetry, natural shape and visibility of the helical rim, and an undisturbed postauricular sulcus.

Closeup lateral views show good symmetry in shape; scars from the ear reduction are well hidden beneath the helical rim and within the helical sulcus. Careful inspection shows the small scar at the splice point of the midhelical rim and lobule.

This young boy's prominent ears resulted from the combined effects of conchal enlargement and deformity of the scapha and helical rim on the right side. The deformity of the right ear differed from the typical constriction in that the antihelical fold was well formed, but the midscapha was sharply folded on itself and the helical rim was tipped forward, with a lack of support to the upper pole of the ear and a degree of lidding as well.

Lateral views demonstrate the difference in the support to the upper pole of the ear and the slight counterclockwise rotation of the right ear in comparison to the left ear.

The concha was reduced initially, as describe previously, and the incision was closed. This first intraoperative view shows the acute fold in the scapha as well as the lid-
ding of the helical rim. The helical rim incision followed the line of the future helical rim, exposing the distorted cartilage.

While the cartilage of the upper pole of the ear was skeletonized, dissecting both posterior and anterior to the helical rim, all adhesions were released. In this case, the cartilage was split through the acute fold, releasing the entire upper pole cartilage to be reshaped and advanced into a natural position by overlapping the cartilage medial to the fold and realigning the helical rim.

After suture fixation, the newly shaped upper pole of the ear was well supported with intercartilaginous sutures, and sutures were placed from scapha to mastoid. The skin was redraped and the slight excess of skin along the helical rim resected. Through-and-through sutures reattached the skin envelope securely to the reshaped cartilage.

The prominence of the left ear was addressed as described, concentrating on the conchal hypertrophy. Although the results at 3 months postoperatively demonstrate a small size discrepancy between the two ears, the natural shape, and symmetrical projection mask this difference.

Closeup lateral views demonstrate the smooth, natural configuration of the antihelix and the well-hidden scars.

This patient illustrates the application of this technique to a moderate constriction. The combined effects of lidding, constriction of the helical rim, and vertical shortness of the ear are evident in group 2B constriction. Although this group of constricted ears characteristically demonstrates shortages in both skin and cartilage, the presence of a bilateral deformity allows correction without concern for the fact that the restructured ear may be relatively small, because the two ears will still match in size.

The approach used in this patient was as described on pp. 1842 through 1845, with initial conchal resection, followed by correction of prominence through the posterior suture placement, then final reshaping of the upper helical rim by a direct anterior approach to the helical lid and constricted rim. Because some additional suture placement from scapha to mastoid may be required in this reshaping of the upper pole, the final posterior closure is delayed until the former area is fully corrected.

The patient is shown 3 years postoperatively with a symmetrical increase in the size of her ears and a pleasing correction of the distorted cartilage shape. The final results of the combined otoplasty procedure illustrate her excellent outcome.

This 10½-year-old girl is shown preoperatively in a candid frontal view and lateral views and at 1 year after otoplasty. The preoperative frontal view shows marked bilateral prominence caused by bilateral conchal hypertrophy and an effaced antihelical fold on the right. The overall ear size bordered on macrotia. There was a prominent Darwin's tubercle on the left, which was excised through a small rim incision following correction of the prominence, as described earlier. Although her ears were asymmetrical and had different underlying cartilage anatomy, the postoperative frontal view shows excellent final symmetry.

This 23-year-old woman presented with concerns related specifically to the prominence and abnormal folding of her upper ear. The preoperative views show atypical lidding and crimping of the helical rim. The mid and lower ears were symmetrical. During correction of an upper pole deformity it is important to avoid changing the shape of the helical rim in the middle third of the ear and secondarily leaving a hidden helix. Using an approach similar to that shown on pp. 1842 through 1845, the upper pole of the ear was approached directly with release of adhesions, reshaping of the helical rim, and support of the new shape with a conchal cartilage graft. Seen 1 year after surgery, the ear has a natural, unoperated appearance with excellent symmetry, correction of the upper pole prominence, and no evidence of overcorrection of the midhelical rim. Lateral views in particular show how the correction of the upper pole deformity not only rounded the curve of the superior helical rim, but also increased the vertical height of the ear.

This 13-year-old girl was frequently teased about her prominent ears and tried to keep her ears as well hidden as possible with her hair. Six weeks after otoplasty, it is apparent how the combined otoplasty approach adapts to treatment of the varied causes of prominence on the two sides.

The closeup views show slight differences in the position of the conchal incision and how the procedure has resulted in a smooth, near-identical antihelical fold on both the side on which it was already formed (*left*) and the side on which it was absent (*right*).

Concluding Thoughts

Ear deformities, even those of a minor degree, can have profound effects on an individual. These effects may persist years after teasing by classmates ceases. Unless all aspects of the deformity are addressed in a systematic manner, correction can result in secondary deformities that are even more disturbing. This chapter presents an in-depth look at how the conchal shape represents the cornerstone of prominent ear deformities and how, coupled with other modifications of the helical rim, conchal release and resection allows correction of the antihelical effacement in a manner that avoids the secondary distortions that trades one deformity for another. Following the approach illustrated in this chapter, one will find the procedures not only more reproducible than others currently in vogue, but also readily applicable to virtually all other nonmicrotia ear deformities.

Clinical Caveats

Correct analysis of each ear deformity is the most important step in otoplasty.

Failure to fully appreciate all elements distorting the ear position and shape (particularly the role of conchal hypertrophy) is likely to result in an unfavorable outcome.

Otoplasty techniques that involve scoring or abrasion of the cartilage all run the potential risk of producing visible cartilage irregularities and a sharp antihelical fold.

Placing the incision for conchal resection too high in the concha will decrease control of the antihelical fold, allowing the cut edge adjacent to the antihelix to spring forward when the antihelix is shaped.

To ensure a tension-free closure of the concha, more cartilage is typically resected than skin, particularly along the inferior concha deep to the antitragus.

Excessive resection of skin or cartilage will pull the antitragus upward and increase prominence of the lower pole of the ear and lobe.

When designing the “squid”-shaped excision, failure to taper the skin excision in its midportion may result in a postoperative telephone-ear deformity.

Preserving the perichondrium on both surfaces of the cartilage will lessen the possibility of subsequent sutures pulling through the cartilage with resultant partial recurrence of the deformity.

Annotated Bibliography

Bauer BS. Congenital and acquired deformities of the ear. In Bentz ML, Bauer BS, Zuker RM, eds. *Principles and Practice of Pediatric Plastic Surgery*, vol 2, St Louis: Quality Medical Publishing, 2008.

This chapter discusses the full spectrum of both congenital and acquired ear deformities, demonstrating otoplasty techniques for treating the range of abnormalities from more commonly recognized nonmicrotia ear problems (constricted ear, cryptotia, and Stahl's ear) to rare and unnamed deformities that plastic surgeons may encounter. It also demonstrates how these techniques can be applied to the reconstruction of acquired ear deformities with similar cartilage and skin deficiencies.

Elliott RA. Otoplasty: a combined approach. *Clin Plast Surg* 17:373-381, 1990.

This paper describes the need to assess both conchal size and antihelical definition to properly address the individual case. It did not describe the combination as a "standard" approach to otoplasty. The conchal incision is also placed considerably higher on the lateral conchal wall.

Erol OO. New modification in otoplasty: anterior approach. *Plast Reconstr Surg* 107:193-202; discussion 203-205, 2001.

This paper describes a combined approach to otoplasty with both conchal resection and reshaping of the antihelix, but does the latter by undermining over the antihelix, scoring of the cartilage, then suture fixation. The scoring is seen to result in irregularities of the antihelix.

Mustarde JC. The correction of prominent ears using simple mattress sutures. *Br J Plast Surg* 16:170-178, 1963.

This classic paper describes suture fixation techniques for correction of ear prominence. The relatively high recurrence rate with this procedure alone underscores the added benefit of the initial conchal resection described in this chapter.

Stark RB, Saunders DE. Natural appearance restored to the unduly prominent ear. *Br J Plast Surg* 15:385-397, 1962.

This article was a predecessor of the authors' technique that described a combination of otoabrasion of the posterior surface of the antihelix to soften the folding with posterior suture fixation. As with other otoabrasion techniques, even with great care, irregularities were still occasionally seen on the surface of the antihelix. There was also a higher recurrence rate than seen with the current technique described in this chapter. Experience with this technique did demonstrate the accessibility of the posterior approach to allow fine tuning of correction through varied suture placement.

Stenstrom SJ. A "natural" technique for correction of congenitally prominent ears. *Plast Reconstr Surg* 32:509, 1963.

This is the classic paper on otoplasty describing anterior scoring of the antihelix to stimulate the folding and shaping of the cartilage. It typifies the type of procedure that can risk irregularities on the surface of the antihelix.

CHAPTER 53

Applied Anatomy of the Nose

ROD J. ROHRICH, WILLIAM P. ADAMS, JR.,
JOEL E. PESSA, JACK P. GUNTER

The nose consists of three elements: framework, support, and external cover. The nasal framework consists of the skeletal components of cartilage and bone. Support is provided by connective tissue and ligaments that hold the framework together. The skin and soft tissue provide the external covering of the nose. These components are intricately related and must be anatomically visualized in every step of the rhinoplasty sequence. In this chapter we will review the clinically relevant anatomy encountered in rhinoplasty.

Principles that must be adhered to in the anatomic sequence of a rhinoplasty include the following:

1. Precise definition of anatomic goals preoperatively
2. Adequate anatomic exposure of the nasal deformity
3. Preservation/restoration of the normal anatomy
4. Correction of the specific deformity using incremental control
5. Maintenance/restoration of the nasal airway

The skin is thinner and more mobile in the upper two thirds of the nose and thicker and more adherent in the distal third in the nasal lobule.

Vessels and nerves pass within the subcutaneous tissue above the muscle. It is important to note the type, texture, and sebaceous content of the skin, because these will affect the final result. Overzealous alteration of the underlying framework in a thin-skinned tip may have a long-term adverse outcome. In contrast, in a patient with thick sebaceous skin, more aggressive alteration of the underlying framework is possible, and necessary, to obtain significant tip definition.

Muscles

Although there are several nasal muscles, two are most clinically significant: the levator alae and depressor septi muscles. The levator labii alaeque nasi assists in keeping the external nasal valve open and can cause functional nasal obstruction with facial paralysis if alar flaring is impaired. The depressor septi nasi, when clinically significant, shortens the upper lip and can decrease tip projection on animation.

The nasal muscles interconnect so that animation of one affects the others. For example, contraction of the lip elevators pulls the transverse nasalis. This has the effect of opening the internal valve by distracting the upper lateral cartilages. Nasal airway patency is therefore also a function of dynamic muscle activity, in addition to proper skeletal and cartilaginous support.

In a cadaver study to define the anatomic variations of the depressor septi muscle, we identified three types of depressor septi muscles. Type I depressor septi muscles (62%) are visible and identifiable and can be traced to full interdigitation with the orbicularis oris from their origin at the medial crural footplate.

Type II muscles (22%) are visible and identifiable, but unlike the first group, these muscles insert into the periosteum and demonstrate little or no interdigitation with the orbicularis oris. In type III muscles (16%), no muscle or only a rudimentary depressor septi muscle is visible.

Routine preoperative examination of rhinoplasty patients should easily identify those who demonstrate a drooping nasal tip and shortened upper lip on animation, particularly when smiling. In such patients (types I and II) dissection and transposition of the distal depressor septi muscles and suturing together of the cut ends reliably and effectively correct this dynamic facial deformity. Dissection and transposition rather than excision of tissue provide fullness to the central upper lip. Follow-up of up to 2 years shows well-maintained aesthetic results without signs of relapse. Specifically, the technique achieves the following goals:

- Enhancement of the tip-lip relationship
- Relative upper lip lengthening
- Relative fullness to the upper lip
- Maintenance of tip rotation/projection on animation

Blood Supply

There has been concern, especially with the growing popularity of the external approach to rhinoplasty, that the transcolumellar incision may compromise the blood supply to the nasal tip. However, one must take into account the considerable blood supply to the nose, with contributions from both the internal and external carotid arteries.

The ophthalmic artery and its branches, anterior ethmoids, dorsal nasal, and external nasal arteries supply the proximal portion of the nose.

The nasal tip area is supplied primarily by branches of the facial artery, including the superior labial and angular vessels, with the lateral nasal branch coursing above the alar groove, and the columellar branches, which are branches of the superior labial vessels. In this dissection, one can see that even the infraorbital artery provides collateral supply to the tip via the nasal arcades.

This vasculature has been confirmed by an angiographic study in 22 fresh cadaver heads injected with lead oxide dye. The lateral nasal vessels were consistently identified 2 to 3 mm above the alar groove in this study. The columellar and lateral nasal arteries arise deep at the nasal base and end in the subdermal plexus at the nasal tip area. The lateral nasal artery was consistently present either bilaterally or unilaterally (100%). The presence of the columellar branches was noted 68.2% of the time; however, there was a predictable crossover arcade between the lateral nasal and columellar branches in 10 specimens in which a transcolumellar incision was made before the dye was injected.

The clinical relevance of this study is twofold. First, it is excessive defatting that jeopardizes the nasal tip supply. In nasal tip procedures the surgeon should reconstruct the underlying framework to redefine the tip rather than defatting the nasal tip, which is anatomically dangerous. The other clinical point is that collateral blood supply enters the nose via the alar arcades. Prior incisions in this region can jeopardize collateral supply to the nasal tip in secondary procedures.

Nasal Vaults

There are three nasal vaults: the bony, upper cartilaginous, and lower cartilaginous vaults.

Bony Vault

The bony vault consists of paired nasal bones as well as the ascending frontal process of the maxilla, which make up the proximal third to half of the nose.

The bones are comparatively narrow and thick above the canthal level. The clinical correlation is that osteotomies are rarely indicated above the canthal level, because it is quite narrow and the bone is thick.

Upper Cartilaginous Vault

The upper lateral cartilages underlie the nasal bones for 6 to 8 mm as well as the lower lateral cartilages in the scroll area between the upper and lower lateral cartilages.

The keystone area is defined by the junction of the upper lateral cartilages with the nasal bones and the septum. It is important to stress the relationship of the upper and lateral cartilages to the septum, especially at the keystone area, where the contour is T-shaped.

Loss of these intricate relationships results in the loss of the dorsal aesthetic lines and a potential inverted-V deformity, as seen on frontal view.

Lower Lateral Cartilaginous Vault

The lower cartilaginous vault comprises the medial, middle, and lateral crura of the lower lateral cartilage.

The support factors for tip projection are:

- Length and strength of lower lateral cartilage and piriform abutment
- Domal suspensory or piriform ligament
- Fibrous connections between the upper lateral and lower lateral cartilage
- Medial crural ligaments
- Anterior septal angle

In a fresh-cadaver study, Adams et al reported the clinical significance of different structures for nasal tip support using open versus closed rhinoplasty techniques. Multiple nasal manipulations using fresh cadaver heads, including cephalic trim,

cephalic trim and interruption of the lower lateral cartilages, dorsal hump resection (1 to 4 mm), submucous resection of the septum, and complete septal removal, were performed using both the open and closed rhinoplasty approaches. Changes in nasal tip support were recorded.

Comparing similar procedures, the mean loss of tip projection for the open approach was 3.43 mm versus 1.98 mm for the closed approach ($p < 0.001$). There was a significantly larger loss of tip projection for the open versus the closed procedure for cephalic trim, cephalic trim plus interruption of the lower lateral cartilage, and cephalic trim/interruption of the lower lateral cartilage/septum removal (all three $p < 0.001$). The differences between the open and closed approaches were attributed to an increase in ligamentous disruption using the open approach. Manipulation of the septum in general resulted in greater losses of tip support for both the open and closed approach.

The combination of skin, ligaments, and cartilage ultimately provides tip support. As progressively more of these structures are disrupted, greater loss of tip projection occurs.

Sheen subdivided the lower lateral cartilage into the medial, middle, and lateral crura. The angle of divergence is formed by the domal angulation of the middle crus.

This is an important factor in determining tip type, specifically whether there is a bulbous versus a boxy tip. The tip-defining points are important: these consist of two equilateral triangles from the supratip area to the apex of the domes to the columellar lobule angle. The surgeon must use these reference points in assessing tip definition and identifying tip asymmetries. Furthermore, a classification system based on the angle of divergence of the middle crura and the width of the domes can aid in the diagnosis and treatment of nasal tip deformities.

Nasal Function

The functional portion of a nose comprises three areas: the septum, nasal valve areas, and turbinates. The septum includes three primary components: the quadrangular cartilage, the perpendicular plate of the ethmoid, and the vomer.

The bony septum is made of the perpendicular plate of the ethmoid, which is in continuity with the cribriform plate. When performing a septal reconstruction and removing posterior septal deviations, the surgeon must perform a sidewise frac-

ture/separation removal of the bony part of the perpendicular plate of the ethmoid so as not to remove or dislodge the cribriform plate, which can cause cerebrospinal fluid rhinorrhea. The most projecting part of the premaxilla is the nasal spine, and it very infrequently needs to be removed or altered. In contrast, the caudal portion of the septum is the most protruding part of the columella and may need to be altered if there is an alar-columellar discrepancy.

The internal nasal valve is defined as the junction between the septum and the caudal border of the upper lateral cartilage. This angle is usually 10 to 15 degrees. This must be preserved or reconstructed with a spreader graft in a primary or secondary rhinoplasty.

Of the three turbinates, the inferior turbinates are the most significant functional component in nasal airway breathing, and this occurs in the lower third of the nasal airway. Submucous resection of the turbinate is indicated for airway correction and yields excellent functional results.

Concluding Thoughts

Nasal anatomy is well defined, and knowledge of this anatomy enables the surgeon to analyze nasal form and shape precisely. Operative goals can be defined to restore normal anatomic relationships, preserving function while improving nasal aesthetics.

Clinical Caveats

Excellent rhinoplasty results can only be obtained if the surgeon has a thorough knowledge of nasal anatomy and understands the surgical relevance of alteration of the anatomic structures.

The type of framework modification is closely related to the skin type.

An active depressor septi muscle can be identified on preoperative clinical analysis, and its modification intraoperatively can enhance the tip-lip complex.

Following the open rhinoplasty approach, the blood supply to the nasal tip is derived primarily from the lateral nasal arteries 2 to 3 mm above the alar groove.

The nasal dorsum is widest at the keystone region.

Multiple structures contribute to nasal tip support, including the strength of the lower lateral cartilage, anterior septal angle, upper lateral cartilage/lower lateral cartilage ligaments, medial crural ligaments, and nasal skin. Clinically one must account for surgical disruption of these structures, taking specific measures to provide nasal tip support, particularly in open rhinoplasty.

The most common cause of functional nasal airway obstruction is inferior turbinate hypertrophy; however, septal deviation or internal or external nasal valve abnormalities must also be considered.

Annotated Bibliography

Adams WP Jr, Rohrich RJ, Hollier LH, et al. Anatomic basis and clinical implications for nasal tip support in open versus closed rhinoplasty. *Plast Reconstr Surg* 103:255-261, 1999.

The purpose of this study was to quantitate, using fresh cadavers, the critical elements for nasal tip support with open versus closed rhinoplasty techniques. Multiple nasal manipulations were performed using fresh cadaver heads and using both the open and closed rhinoplasty approaches. In the end, the authors found that the open approach for rhinoplasty results in a significantly increased loss of tip projection when compared with the closed technique because of the larger disruption of ligamentous support.

Gunter JP, Rohrich RJ. The external approach for secondary rhinoplasty. *Plast Reconstr Surg* 80:161-174, 1987.

A systematic approach, using the external rhinoplasty technique, is presented to aid the plastic surgeon in obtaining improved aesthetic and functional results in patients with postoperative nasal deformities. In over 100 external rhinoplasties, there were no problems with the stairstep transcolumellar incision used to provide complete visualization of the underlying nasal framework. Three case reports are presented to demonstrate the indications and versatility of the external approach in secondary rhinoplasty.

Janeke JB, Wright WK. Studies on the support of the nasal tip. *Arch Otolaryngol* 93:458-464, 1971.

This is one of the first articles to delineate the support structure of the nose. They define four areas of support: the intercartilaginous ligament, the sesamoid complex, the ligamentous sling between the lower lateral cartilages, and the attachment of the medial crura to the caudal septum.

Rohrich RJ, Gunter JP, Friedman RM. Nasal tip blood supply: an anatomic study validating the safety of the transcolumnellar incision in rhinoplasty. *Plast Reconstr Surg* 95:795-799, 1995.

The nasal tip blood supply was studied through anatomic dissections and microangiography in 31 fresh cadaver specimens. Transcolumnellar (external rhinoplasty) incisions were performed in 11 of these cadavers before dye injection. A consistent crossover flow (100%) was seen from the lateral nasal artery arcades to the distal aspect of the transected columellar branches. We conclude that nasal tip blood supply is derived primarily from the lateral nasal arteries, with a variable contribution from the columellar arteries. Collateral flow to the nasal tip may be provided by branches of the ophthalmic artery. The external rhinoplasty transcolumnellar incision does not compromise nasal tip blood supply unless extensive tip defatting or extended alar base resections (above the alar groove) are performed.

Sheen JM. Achieving more nasal tip projection by use of a small autogenous vomer or septal cartilage grafts. A preliminary report. *Plast Reconstr Surg* 56:35-40, 1975.

Sheen's classic article describes the relationship of the nasal tip to the dorsum, emphasizing the supratip break and tip projection. He introduces the use of small pieces of autogenous cartilage and vomer and the shaping required to re-create the proper dorsum-tip relationship, a clinical application of Peer's early work on the transplantation of autologous tissues.

CHAPTER 54

Clinical Decision-Making in Rhinoplasty

JEFFREY E. JANIS, JAMIL AHMAD, ROD J. ROHRICH

Evaluation

When initially evaluating a potential patient for rhinoplasty, we resist the temptation to immediately launch into a comprehensive facial analysis, and instead concentrate on evaluating the patient's desires and expectations. Proper patient selection is vital to a successful outcome. Some patients will be dissatisfied with their postoperative result regardless of how well surgery has been executed. This emotional dissatisfaction supersedes technical failure as the most common cause of poorly perceived results in our practice. (See Chapter 55 for additional discussion.)

To preoperatively identify potential problem patients, we ask patients to first elucidate what issues they have. We encourage them to be as specific as possible, listing their concerns in order of importance, and to do so in their own words. A handheld mirror is useful in aiding them to pinpoint their areas of concern. The patient's desires are then documented verbatim in the chart. Frequently the patient will state his or her desires in general terms: "I just want a better nose. What would you do?" This has been a red flag in our practice, because it usually is a reflection of general dissatisfaction, poorly thought-out desires, or a poor self-image. We politely redirect these patients in an attempt to ascertain what specifically bothers them about their nose.

The surgeon should be wary of patients who express a disproportionate concern about a minimal deformity. Regardless of the degree of deformity, however, if the skill and expertise required to correct the deformity lie outside the surgeon's technical ability, the patient should be referred to another surgeon who possesses the appropriate knowledge and skill.

Other red flags in rhinoplasty include patients who desire a result that cannot be predictably or reliably delivered or is outside the realm of the “aesthetic norm,” those who appear to be angry or litigious as a result of a previous rhinoplasty, or where a connection is not made between the surgeon and patient. This last criterion is admittedly vague, but we place a tremendous amount of stock in the development of an interpersonal relationship with our patients, and if that relationship cannot be forged, for whatever reason, then we decline to perform the operation. In other words: *Do not operate on a patient you don’t like.*

Nasal History

A full and complete nasal history should be obtained, including any history of trauma, previous nasal/septal/sinus surgeries, allergies and/or sinus problems, tobacco use, and illicit drug use. A list of current medications should also be obtained (both nasal and nonnasal medications). Nonsteroidal antiinflammatory drugs (NSAIDs), certain herbal supplements, and fish oil may increase bleeding complications after surgery and should be discontinued at least 7 to 10 days before a rhinoplasty procedure.

Anatomic Features

Proper nasofacial analysis is paramount to a successful result. This not only includes the nose proper, but also the nose within the context of the face, especially the lip-chin complex. Each individual’s nose is different; therefore each operative plan should be individualized. The development of the operative plan depends on native nasal anatomy and morphology, its relative relationship to the rest of the face, and the patient’s goals and desires. Computer imaging is routinely used to help demonstrate the potential outcome as well as to identify preoperative asymmetries for the patient. However, it should be made clear to the patient that computer imaging does not guarantee a specific result.

Nasal Analysis for Rhinoplasty

- Assess the level of patient concern versus the deformity.
- Identify potential problem patients.
- Assess the patient’s skin type, skin thickness, and skin texture.
- Analyze the relationship of the nose to the face based on anteroposterior, lateral, and basal views.
- Perform an intranasal examination to assess functional aspects of the nose.

The type, thickness, and texture of the patient's skin are assessed first. Thicker skin tends to camouflage changes to the underlying osteocartilaginous framework and thus may necessitate more aggressive manipulation of the underlying framework to produce an appreciable change. Conversely, thinner skin tends to reveal even minor changes to the underlying framework. We have found thinner-skinned patients more challenging in general than thicker-skinned patients, because there is less room for error. Patients with thicker, more sebaceous skin tend to have more postoperative edema, especially in the tip or lobule area. This assessment of native skin quality will factor into the development of the operative plan and the power of the techniques selected to achieve the desired result (such as the use of grafts versus tip suturing alone).

Next, a meticulous systematic analysis of the nose and face is performed. Initially we evaluate potential anomalies of the underlying facial skeleton, including the maxillomandibular relationship. The face is divided into thirds using horizontal lines adjacent to the hairline, brow (at the level of the supraorbital notch), nasal base, and *menton*. The upper third is the least important, because it is the most variable. The lower third of the face is then subdivided into thirds by visualizing a horizontal line between the oral commissures (*stomion*). The upper third of this subdivision lies between the nasal base and the oral commissures, and the lower two thirds between the commissures (*stomion*) and the *menton*. If disproportions exist, the patient may have underlying craniofacial anomalies (such as vertical maxillary excess) that may need to be addressed.

The nasal length (radix-to-tip distance, or RT) should be equivalent to the stomion-to-menton distance (SM), as described by Byrd and Hobar.

A natural horizontal facial plane is determined by drawing a line perpendicular to a plumb line superimposed over the head in repose and the eyes in straightforward gaze. This will be used as a future reference for further analysis.

The lip-chin relationship is assessed by dropping a vertical line from a point one half the ideal nasal length tangential to the vermilion of the upper lip. The lower lip should lie no more than 2 mm behind this line. The ideal chin position varies with sex, with the chin lying slightly posterior to the lower lip in women, but equal to the lower lip in men. If there is a discrepancy in these relationships, orthodontics, orthognathic surgery, or a chin implant may be necessary to improve facial harmony.

Nasal Deviation

Nasal deviation is then assessed by drawing a line from the midglabellar area to the menton, bisecting the nasal ridge, upper lip, and Cupid's bow. In patients with normal occlusion, this line will also pass between the central incisors. Any deviation of the nose from this line typically indicates an underlying septal deviation that will need to be addressed during surgery to correct the deformity.

Dorsum

The nasal dorsum is then assessed on anteroposterior or frontal photographs of the patient. The curvilinear dorsal aesthetic lines are traced from where they originate at the supraorbital ridges to the tip-defining points, slightly diverging from each other along the dorsum during their course. Ideally, the width of the dorsal aesthetic lines should match the width of either the tip-defining points or the interphiltral distance. These lines may be ideal, narrow, wide, asymmetrical, or ill defined.

Bony Base

The width of the bony base relative to the alar base is then assessed. The bony base width should be 80% of the normal alar base width, and a normal alar base width is equal to the intercanthal distance, or the width of the palpebral fissure. If the bony base is greater than 80% of the alar base width (assuming the alar base width is normal), it is likely that osteotomies will be required to narrow the bony base. Because men tend to have a wider bony base than women, it is important not to make the dorsum overly narrow in men, because this could feminize the nose.

Alar Base

The alar base itself is analyzed as well as the alar rim morphology. If the alar base width is greater than the intercanthal distance, it must be determined whether this is the result of a narrow intercanthal distance, a true increased interalar width, or alar flaring. If the intercanthal distance is smaller than one eye width, it is better to maintain a slightly wider alar base. If there is true increased interalar width, a nostril sill resection may be indicated. If the increase in width is secondary to alar flaring (more than 2 to 3 mm outside the alar base), an alar base resection should be considered. The alar rims should also be assessed for symmetry and should flare slightly outward in the inferolateral direction.

While the frontal view is still being addressed, the tip is assessed to determine the supratip break, the tip-defining points, and the columellar-lobular angle. These points serve as landmarks to draw two equilateral triangles with their bases opposed. If these triangles are asymmetrical, the underlying reason should be investigated, and the patient will likely require tip modification.

Alae

The final assessment on frontal view is of the outline of the alar rims and the columella, which should resemble a seagull in gentle flight, with the columella lying just inferior to the alar rims. If the curve is too steep, the patient likely has an increased infratip lobular height that will need correction. On the other hand, if the curve is flattened, it is likely the patient has decreased columellar show, which may require columellar augmentation or alar rim modification. Facets of the soft tissue triangles should be noted, because these may require alar contour grafts to prevent alar notching.

ANTEROPOSTERIOR/FRONTAL ASSESSMENT OF THE NOSE AND FACE

*Basal View*

The basal view of the nose is addressed next, with the outline of the nasal base describing an equilateral triangle with a lobule-to-nostril ratio of 1:2. The nostril itself should have a teardrop-like geometry, with the long axis from the base to the apex oriented in a slight medial direction.

Lateral View

The lateral view is analyzed, beginning with the position and depth of the nasal root at the radix. The nasofrontal angle connects the brow and dorsum through a soft concave curve. The apex of this angle should lie between the upper lid eyelashes and the supratarsal fold, with the eyes in a natural horizontal gaze. Although this angle can vary from 128 to 140 degrees, it is ideally 134 degrees in women and 130 degrees in men. Other important reference measurements from this view include the nasion–medial canthal distance, which should be approximately 15 mm, and the nasion–corneal plane distance, which is approximately 11 mm.

While still concentrating on the lateral view, the surgeon must remember that the perceived nasal length and tip projection can be altered by the position of the nasofrontal angle. For instance, if the nasofrontal angle is positioned more anteriorly and superiorly than normal, the nose will appear elongated, the nasofacial angle will be decreased, and the tip projection will appear diminished (*yellow line*). On the other hand, if the nasofrontal angle is positioned too posteriorly and/or inferiorly, the nose will appear shorter, and the tip more projecting (*red line*). Ideally, the nasofacial angle (as defined by the junction of the nasal dorsum with the vertical facial plane) should measure 32 to 37 degrees.

Tip Projection

The examiner addresses tip projection next, while looking at the lateral view. Although several methods have been described to assess this, we prefer the following two ways. In a patient with normal upper lip projection, we begin by drawing a line from the alar-cheek junction to the tip of the nose. The tip projection is considered normal if 50% to 60% of the tip lies anterior to a vertical line adjacent to the most projecting part of the upper lip. The tip is considered to be overprojecting if more than 60% of the tip lies anterior to this reference line and may therefore require deprojection. Conversely, if less than 50% of the tip lies anterior to the line, the projection may need to be augmented (in any number of ways).

The second method we use to help assess tip projection is to compare it with the alar base width (they should be equal) (*left*), and compare the ratio of nasal length (radix-to-tip, RT) to the tip projection (alar base-to-tip). In the latter, the ideal tip projection is $0.67 \times \text{RT}$ (*right*).

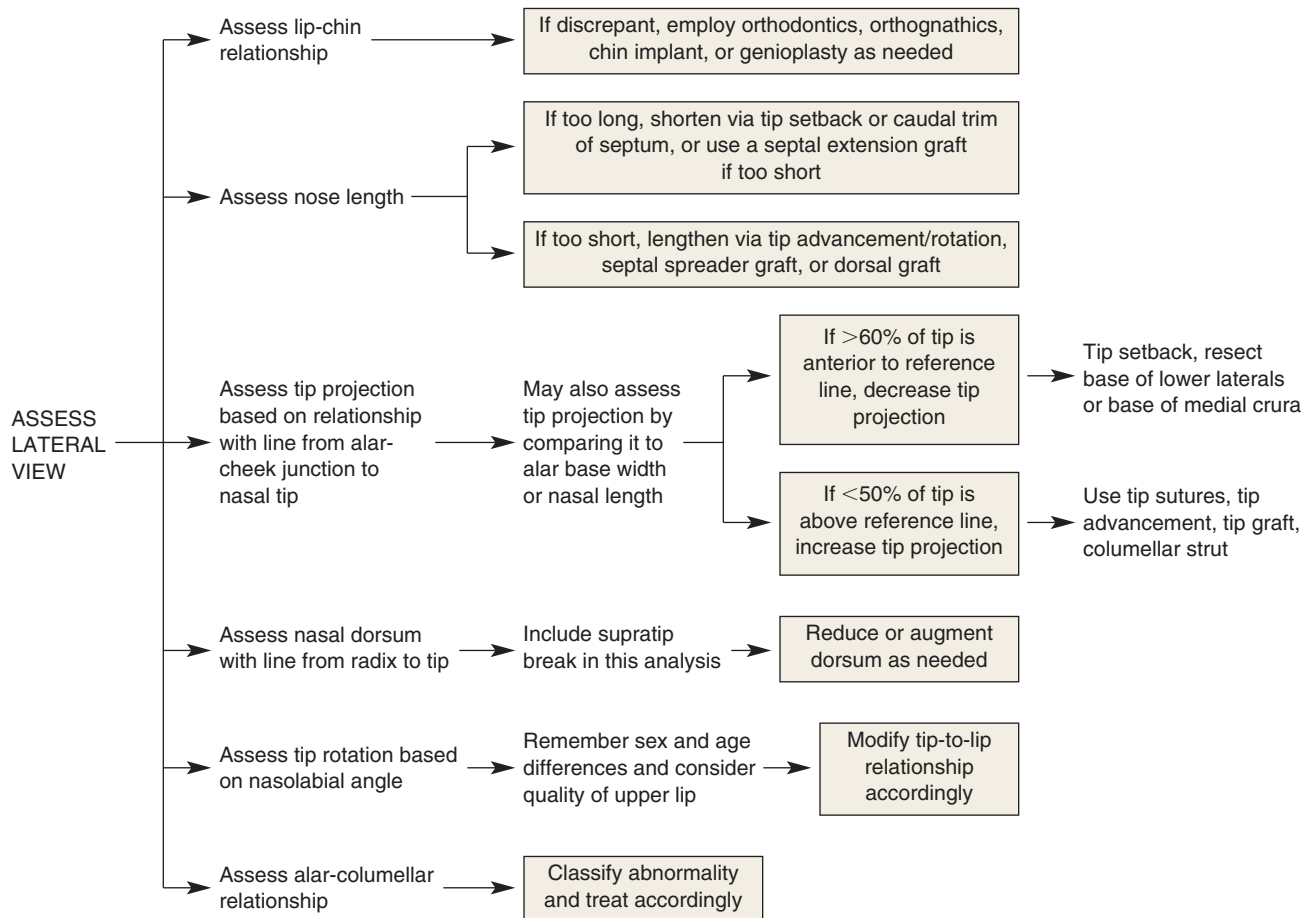

After the tip projection is assessed, the dorsum is analyzed. The aesthetic nasal dorsum should lie approximately 2 mm behind and parallel to a line from the radix to the tip-defining points in women, but in men it should be slightly higher to avoid feminizing the nose.

The degree of supratip break is appraised when the nasal tip projection and dorsum are evaluated. A slight supratip break is preferred in women but not in men. This gives the nose more definition and distinguishes the dorsum from the tip.

The nasolabial angle is used to determine the degree of tip rotation. This angle is obtained by measuring the angle between a line coursing through the most anterior and posterior edges of the nostril and a plumb line dropped perpendicular to the natural horizontal facial plane. This angle should be 95 to 100 degrees in women and 90 to 95 degrees in men.

LATERAL ASSESSMENT OF THE NOSE

The nasolabial angle should not be confused with the columellar-labial angle, which is formed at the junction of the columella with the upper lip/infratip lobule. Increased fullness in this area is usually caused by a prominent caudal septum and gives the illusion of increased rotation, even though the nasolabial angle is normal. This angle is normally 30 to 45 degrees.

The alar-columellar relationship is then assessed (lateral and frontal views). A line is drawn through the long axis of the nostril, and a perpendicular line is drawn from the alar rim to the columellar rim that bisects this axis. The distance from the alar rim (point A) to the long-axis line (point B) should equal the distance between the long-axis line and the columellar rim (point C) if the alar-columellar relationship (ACR) is normal ($AB = BC \approx 2 \text{ mm}$).

If these measurements are not normal, the deformity can be categorized into six classes. Classes I to III describe increased columellar show, whereas classes IV to VI demonstrate decreased columellar show. These may be treated differently, depending on the class of deformity.

The above proportions generally apply to white women. Generally, the male face tends to have a squarer, less rounded appearance, with stronger, more pronounced features. The key differences in men are as follows:

The male dorsum tends to be straighter and wider, with decreased concavity at the superciliary ridges.

The male nasal dorsal profile should hug a line drawn from the radix to the tip-defining points instead of falling 2 mm behind and parallel to this line, as seen in women.

There should be no supratip break.

The tip rotation in men is slightly less than in women (90 to 95 degrees versus 95 to 100 degrees in women), inasmuch as men have less nostril show as a result of a longer nasal dorsum.

Men have a stronger chin, abutting the plumb line drawn tangential to the upper lip (versus 2 to 3 mm posterior to this line in women).

In general, men have a broader, more bulbous nasal tip.

Male skin is usually thicker, masking the amount of change that can be seen.

NOTE: These proportions are general guidelines and will vary within sex and race. They are only meant to be used as a systematic method of analysis of general proportions and relationships. The plan for each nose should be individualized to the patient’s facial structure and tempered by the patient’s desire to create nasofacial harmony and balance.

Systematic Approach to Rhinoplasty Planning*

A thorough history should be taken, with emphasis on past facial or nasal surgery, facial/nasal trauma, nasal function, and ease of breathing.
 The patient's desired nasal shape and aesthetic outcome are systematically delineated.
 An intranasal examination is done with a headlight and speculum.
 Imaging is performed: anteroposterior, lateral, and basal views.
 The images are reviewed with the patient, emphasizing what is and is not surgically possible.
 A systematic, surgeon-directed review of imaging forms the basis of a line-by-line surgical plan.
 The surgical plan is reviewed with the patient before surgery.
 The surgical plan is carried out.

*All secondary and posttraumatic rhinoplasties are performed using an open approach; a closed approach is considered for isolated dorsal deformities or minor tip modifications.

Surgical Approach

There are two basic incisional approaches to rhinoplasty: the open technique and the closed, or endonasal, technique. Each has its staunch proponents, and each has been used successfully in the practice of rhinoplasty.

Choosing the Best Option

	Open Approach	Endonasal Approach
Binocular visualization	+++	++
Evaluation of complete deformity without distortion	+++	+
Precise diagnosis and correction of deformities	+++	+
Direct control of bleeding	++	+
Nasal incision	+	+++
Operative time	+	++
Prolonged nasal tip edema	+	+++

Degree of effectiveness indicated by the number of pluses.

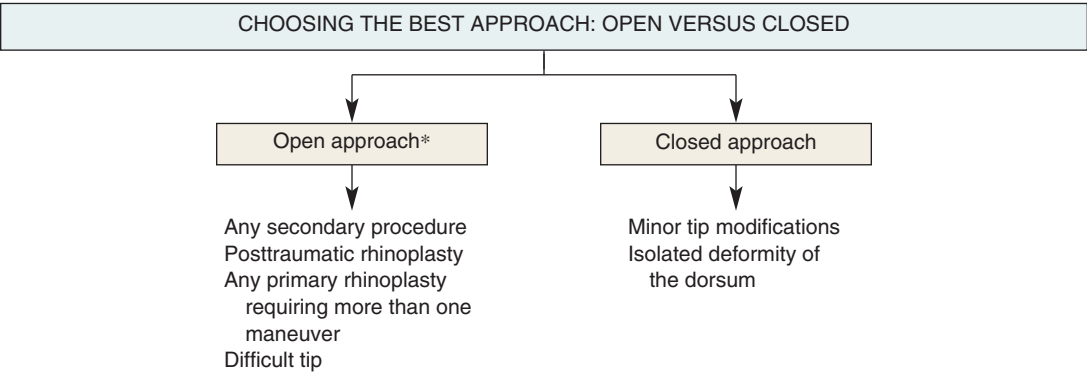

The open approach involves a transcolumellar incision, which can assume varying geometries, depending on the surgeon's preference. We prefer a stairstep configuration, because it lends itself well to realignment and facilitates reapproximation while

breaking up the scar (preventing contracture deformities and camouflaging the result). The open approach also involves skeletonizing the underlying osteocartilaginous framework, which gains enormous exposure for its manipulation and correction of deformities.

The closed, or endonasal, approach can be performed using a cartilage delivery approach or a nondelivery approach. The delivery approach involves an intercartilaginous incision, a marginal incision, and either a transfixion or hemitransfixion incision with subsequent transposition of the lower lateral cartilages to a location outside of the skin envelope. A nondelivery approach uses either a transcartilaginous incision or an eversion (retrograde) incision, with the lower lateral cartilages remaining in their native positions. Manipulation and modification of the osteocartilaginous framework are then carried out, although the skin envelope is not reflected, as in the open approach.

We perform the vast majority of our operations using the open approach, because it affords excellent exposure and control, grants the ability to manipulate the osteocartilaginous framework under direct visualization, and has minimal negative consequences, other than an external scar and occasional prolonged tip edema, which resolves in virtually all of our patients. We are able to obtain predictable and reproducible results using this type of approach. Furthermore, we think the tradeoff of increased accuracy and versatility using the open approach is worth the tradeoff of an external scar that typically heals very well. We rarely have a patient who objects to the transcolumellar scar, since it usually is invisible at conversation distances.

We reserve a closed approach for isolated deformities of the dorsum or when minor tip modifications are necessary. However, all secondary rhinoplasties and posttraumatic rhinoplasties are performed exclusively with the use of the open approach in our hands.

*Open approach affords excellent exposure of all major components of the nose.

Concluding Thoughts

The evolution of rhinoplasty has been long; advances in analysis and techniques have led to the ability to produce a predictable result, yet rhinoplasty remains one of the most challenging procedures in all of plastic surgery. Just as there is a fine line (perhaps only 1 or 2 mm) between an excellent result and a good one, the line is just as fine between an acceptable and an unacceptable result. The surgeon must become familiar with nasal anatomy and the limitations of techniques used to manipulate that anatomy. Complications may result (either from iatrogenic injury or from adverse cicatricial formation) that will require secondary revision. The surgeon should be able to address these complications as well, or at least know his or her own limitations and refer the patient to someone who can rectify the problem.

Much has been made about the incisional approach throughout this evolution. At one point, most rhinoplasties were performed using the closed approach. The pendulum swung to favor the open approach and now has settled somewhere in between, as is the case with most concepts in plastic surgery. In the end, the surgeon should choose the approach that he or she is most comfortable with. Furthermore, it cannot be overemphasized that *the proportions and relative relationships introduced in this chapter must be individualized to every patient*. There is no cookie-cutter or cookbook approach to rhinoplasty. The ultimate successful result will be determined by proper patient selection, the ability to accurately diagnose the deformity and generate an operative plan, and the capacity to execute that plan in a predictable, reliable, and reproducible fashion based on the principles described here.

CHAPTER 55

Primary Rhinoplasty

JEFFREY E. JANIS, JAMIL AHMAD, ROD J. ROHRICH

Rhinoplasty is one of the most complex and challenging operations in plastic surgery. The rhinoplasty surgeon must have a thorough understanding of the three-dimensional anatomy of the nasal region, a proficiency in nasal and facial analysis, and a firm grasp of the core concepts in manipulating nasal soft tissues, cartilage, and bone. The surgeon must also be able to visualize the dynamic interplay between these structures and have an aesthetic eye to craft a result that will produce a balanced, harmonious nose in relationship to the rest of the face. The initial operation is critical to the long-term result, because the tissues are virginal and undistorted by prior operative procedures.

Evolution of Technique

Aesthetic rhinoplasty has its roots in nasal reconstruction. The first recorded treatment of nasal injuries dates back to approximately 3000 BC, as recorded on the Egyptian Edwin Smith surgical papyrus. Reconstructive surgery for nasal deformities is described as early as 600 BC by Sushruta. After a long period of quiescence during the Dark Ages, descriptions of nasal reconstruction again appeared as the Renaissance brought forth advances in science and medicine. The Indian methods for nasal reconstruction with forehead and cheek skin were practiced and modified by Italian surgeons into the Italian method, using arm skin to reconstruct the nose. In the early nineteenth century, German surgeons including Carl von Graefe and Johann Friedrich Dieffenbach continued to develop methods for nasal reconstruction; Dieffenbach was one of the first to describe nasal surgery for aesthetic improvement of the nose.

John Orlando Roe, an American otolaryngologist, is credited with describing the first aesthetic rhinoplasty and introducing the endonasal approach. In 1887, Roe published “The Deformity Termed ‘Pug Nose’ and Its Correction, by a Simple Operation” and in 1891, “The Correction of Angular Deformities of the Nose by a Subcutaneous Operation.” Roe’s descriptions preceded those of Jacques Joseph, a German orthopedic surgeon often regarded as the father of modern rhinoplasty, given his contribution to the analysis, classification, and repair of various nasal deformities, outlined in his two-volume textbook on plastic surgery of the nose.

In the first half of the twentieth century, the emergence of plastic surgery as a specialty was spurred forward by experience gained reconstructing devastating war injuries. The second half of the twentieth century saw significant contributions to the rhinoplasty literature, with gains in preoperative assessment and diagnosis, management of the nasal airway, cartilage-grafting techniques, and popularization of the open approach to rhinoplasty. The open approach was first described by Aurel Réthi

of Budapest in 1921 but did not gain popularity. In the 1960s his approach was rediscovered by Ante Sercer of Zagreb and introduced to North America by his associate, Ivo Padovan, in 1970. William Goodman of Toronto was the first North American to adopt the open approach, and this technique has gained in popularity since the 1980s.

Indications and Contraindications

Rhinoplasty can be performed for many indications, which fall along a spectrum from purely functional to purely aesthetic. However, each individual's nasal anatomy must be taken into account when deciding whether the patient is a good surgical candidate, and what approach should be used to address the problem. No single approach is appropriate for all situations.

Obviously, there can be great advantages for the patient when rhinoplasty is properly performed. Patients who suffer from nasal airway obstruction can achieve significant amelioration, if not total eradication, of their symptoms. Frequently these patients have had difficulty breathing for several years. Whether the deformity is congenital or traumatic, patient satisfaction is extremely high after corrective surgery is performed.

Similarly, a patient who undergoes rhinoplasty for purely aesthetic reasons stands to benefit significantly with respect to self-image and self-esteem after a successful rhinoplasty. One must be wary, however, of patients who perceive a significant deformity in themselves when the deformity appears minor to the surgeon. Such patients may never be satisfied with the outcome, no matter how well the rhinoplasty is executed (see Chapter 1). Multiple preoperative visits are necessary to completely understand not only what the patient desires, but also to confirm whether the patient's expectations are realistic.

The Open Versus the Endonasal Approach

In modern rhinoplasty, both the open and the endonasal (closed) approach have their staunch proponents. The open approach continues to gain in popularity over the endonasal approach for both primary and secondary rhinoplasty. There are advantages and disadvantages to both techniques, with the correct approach determined by the patient's anatomic deformity and the surgeon's experience. Clearly, what is performed to alter the underlying anatomy is far more important than the type of incision used.

Open Rhinoplasty Approach Rationale

Distinct Advantages	Potential Disadvantages
Binocular visualization	External nasal incision (transcolu- mellar scar)
Evaluation of complete deformity without distortion	Prolonged operative time
Precise diagnosis and correction of deformities	Protracted nasal tip edema
Allows use of both hands	Columellar incision separation
More options with original tissues and cartilage grafts	Delayed wound healing
Direct control of bleeding with electrocautery	
Suture stabilization of grafts (invisible and visible)	

Despite the disadvantages to the open approach, in our experience we have not had patient dissatisfaction related to these specific factors, other than prolonged nasal tip edema. As long as the expectation level is set preoperatively, this has not proved to be a problem.

Those who favor the endonasal approach to rhinoplasty submit that the advantages offered by the open approach are outweighed by its disadvantages.

Endonasal Approach

Advantages	Disadvantages
Leaves no external scar	Requires experience and great reliance on accurate preoperative diagnosis
Limits dissection to areas needing modification	Prohibits simultaneous visualization of the surgical field by a teaching surgeon and students
Permits creation of precise pocket so graft material fits exactly without need for fixation	Does not allow direct visualization of nasal anatomy
Allows percutaneous fixation when large pockets are made	Makes dissection of alar cartilages diffi- cult, particularly in cases of malposition
Promotes healing by maintaining vascular bridge	
Encourages accurate preoperative diagnosis and planning	
Produces minimal postsurgical edema	
Reduces operating time	
Results in fast patient recovery	
Creates intact tip graft pocket	

We prefer the open approach, in general, because it provides full visualization of the nasal framework to more accurately diagnose the cause of the nasal airway obstruction or the aesthetic deformity. Manipulation of the various structures, from the dorsum to the septum to the tip, can be done with precision and can yield reproducible results. We strongly recommend the open approach when addressing a posttraumatic deformity or in secondary/revisional surgery, as well as when complex tip modifications are necessary.

We find the endonasal approach to be advantageous in patients with an isolated dorsal hump deformity or when minimal modification of the tip is required. In these instances, we prefer access through a marginal incision (approximately 1 mm cephalad to the caudal margin of the lateral crus). We combine this with an intercartilaginous incision in cases of minor tip refinement to allow adequate cartilage delivery and exposure. If the caudal septum needs to be corrected as well, we perform a concomitant hemitransfixion or transfixion incision.

Pertinent Anatomy

As in every other area in plastic surgery, thorough knowledge of anatomy is paramount to obtaining a superior result. The nose is divided into external skin and soft tissue, the underlying osteocartilaginous framework, and ligamentous support. Rhinoplasty surgeons must be familiar with each structure's native morphology and its variants and must have an appreciation for the dynamic interplay between the components.

Skin

The thickness, mobility, and sebaceous character of the nasal skin vary along its length, with the upper two thirds being thinner, more mobile, and less sebaceous than the inferior third. The nasal dorsum thickness averages approximately 1300 microns, whereas the lobule skin thickness averages 2400 microns. A straight dorsum actually has a slight underlying convexity of its osteocartilaginous framework in the cephalic area; therefore a straight dorsal profile is actually produced by the combination of this convexity in the osteocartilaginous framework with the variation in dorsal skin thickness.

Some ethnic subgroups, such as those of African descent, Hispanics, and those of Mediterranean descent, can have thicker, more sebaceous skin. These differences are important, because the skin over the underlying nasal framework can either reveal or mask changes depending on its characteristics. For instance, it is advisable to err on the conservative side when operating on a white woman with thin skin compared with a man of African descent with thick, sebaceous skin. More dramatic manipulation to the underlying nasal framework will be necessary in the patient with thick skin to obtain an appreciable change in the external appearance.

Muscle

Two muscles, in particular, are important in rhinoplasty—the levator labii alaeque nasi and the depressor septi nasi. The levator labii alaeque nasi helps to maintain the patency of the external nasal valve, whereas the depressor septi nasi, if overactive, can shorten the upper lip, cause a transverse upper lip crease, and alter tip projection.

Evaluation of the depressor septi nasi is routine in our preoperative assessment. Its effect on depressing the nasal tip and shortening the upper lip can be appreciated in some patients on animation (especially when smiling). In the subgroup of patients in whom this muscle significantly alters the nasal appearance, we dissect and transpose the muscle. By doing so, several goals are achieved:

1. Enhancement of the tip-lip relationship
2. Relative upper lip lengthening
3. Relative fullness to the upper lip
4. Maintenance of tip rotation/projection on animation

Blood Supply

The blood supply to the nose is derived both from branches of the ophthalmic artery and branches of the facial artery. It is important to note the vascularity to the nasal tip because an open rhinoplasty approach using a transcolumellar incision will transect the columellar vessels (when present), leaving the lateral nasal and dorsal nasal arteries as the remaining blood supply. In our 1995 study, we found the lateral nasal arteries to be present (either singularly or bilaterally) in 100% of cases, with the columellar branches present 68.2% of the time. Since the lateral nasal vessels are found approximately 2 to 3 mm above the alar groove, extended alar resections to this level are prohibited, because injury to these vessels after the transcolumellar approach would severely compromise blood flow to the nasal tip. Furthermore, one must be extremely cautious when debulking the nasal tip after an open approach, because the subdermal vascular plexus connecting the dorsal nasal and lateral nasal blood supplies may be damaged, leading to a similarly disastrous result, with necrosis of the nasal tip skin.

Tardy and Toriumi studied the vascular and lymphatic anatomy of the nose and determined that the transcolumellar incision itself did not compromise major venous or lymphatic outflow. Furthermore, they recommend dissection just above the perichondrium in the deep areolar plane, leaving the musculoaponeurotic layer intact, which preserves the major arterial vascular supply and avoids damage to the venous and lymphatic vasculature that lies in a more superficial (subcutaneous) plane. In this way, bleeding and postoperative edema are minimized.

Nasal Vaults

The osteocartilaginous nasal framework can be subdivided into three separate vaults: bony, upper cartilaginous, and lower cartilaginous. The bony vault constitutes the upper third to half of the nose and is made up of the paired nasal bones and the ascending frontal process of the maxilla. It is important to note that the nasal bones are narrowest and thickest above the level of the medial canthi. As a result, osteotomies are rarely indicated above this level.

The upper cartilaginous framework begins where the nasal bones overlap the upper lateral cartilages (ULCs) and septum for 4 to 6 mm, creating what is known as the keystone area. This area should be the widest part of the dorsum, and resembles a T shape in cross-section. The remainder of this vault is composed of the paired ULCs and dorsal cartilaginous septum. Overresection during dorsal hump reduction in this area can lead to deformities such as the inverted-V deformity and/or disruption of the dorsal aesthetic lines. A component dorsal hump reduction is advised to avoid these complications.

The lower cartilaginous framework begins where the ULCs interdigitate with the lower lateral cartilages (LLCs) in what is called the scroll area. The lower lateral cartilages comprise the medial, middle, and lateral crura. These cartilages are connected to each other, the ULCs, and the septum by fibrous tissue and ligaments. Disruption of these ligaments can result in diminished tip projection during rhinoplasty. Thus if these structures are violated, maneuvers that increase tip support (for example, columellar struts, extended spreader grafts, batten grafts, suture techniques) may be necessary.

Nasal Function

The septum, turbinates, and internal and external nasal valves serve as the anatomic functional foundation for the nose, contributing to respiration, filtration, humidification, temperature regulation, and protection. The septum is made up of the septal cartilage, the perpendicular plate of the ethmoid, the nasal crest of the maxilla, and the vomer.

Deformities in the septum can lead to significantly impaired airflow through the nose, as well as compensatory turbinate pathology. When addressing septal deformities, it is important to assess all septal components. When performing a septal resection, it is important to remember that the perpendicular plate of the ethmoid is contiguous with the cribriform plate posterosuperiorly. Therefore, a sidewise fracture of the perpendicular plate should be performed with care to prevent iatrogenic fracture of the cribriform plate and its untoward consequences (for example, cerebrospinal fluid rhinorrhea, potential ascending infection/meningitis). Restoration of a normal straight septum will help reestablish laminar airflow.

The turbinates help to guide the transport of air during respiration and condition/humidify inspired and expired air. These structures are mucosa-lined extensions of the lateral nasal cavity, and undergo a normal autonomically mediated cycle of expansion and contraction. Of all the turbinates, however, it is the inferior turbinate that has the greatest impact on airway resistance, providing up to two thirds of the total airway resistance from its most anterior aspect. However, overresection of the anterior inferior turbinate can have a deleterious effect on its regulatory and physiologic functions, and can lead to crust formation, bleeding, and nasal cilia dysfunction.

The internal nasal valve can contribute up to 50% of the total airway resistance, and is the narrowest segment of the nasal airway. It is composed of the angle formed by the intersection of the nasal septum and the caudal margin of the upper lateral cartilage, and is usually 10 to 15 degrees. In some cases, the anterior portion of the inferior turbinate may be a significant contributor to the decrease in the cross-sectional area of this region. Patients with short nasal bones and long, poorly supported ULCs have a propensity to have collapse at this area. Traditionally, lateral traction on the cheek (positive Cottle's sign) diagnoses collapse of the internal nasal valve and signals the need for spreader grafts to increase the valve angle and stent the airway open.

The external nasal valve is the cartilaginous vestibule bounded by nares and lateral alar sidewalls. It is caudal to the internal valve. Obstruction at this area may be caused by foreign bodies, weak or collapsed lower lateral cartilages, loss of vestibular skin, or scar tissue. Several options are available to reestablish proper airflow through this area, including alar contour grafts, lateral crural strut grafts, lateral crural cephalic turnover flaps, lysis of adhesions, scar revision, mucosal grafts, skin grafts, or composite grafts.

Preoperative Assessment

Initial Consultation

Before proceeding with a rhinoplasty, it is important to completely evaluate the patient's motivations and expectations for surgery to determine whether the patient is a suitable surgical candidate. Gunter and Gorney have both commented on "danger signs" that may be exhibited by certain patients. Patients that meet these criteria should be approached with caution because surgical intervention may not be in the

best interests of either the patient or the surgeon. Gunter identified the following 13 danger signs that may signify underlying psychological issues:

1. Minimal disfigurement
2. Delusional distortion of body image
3. Identity problem or sexual ambivalence
4. Confused or vague motives for wanting surgery
5. Unrealistic expectations of change in life situation as a result of surgery
6. History of poorly established social and emotional relationships
7. Unresolved grief or currently in a crisis situation
8. Present misfortunes blamed on physical appearance
9. Older neurotic man who is overly concerned about aging
10. Sudden dislike for one's anatomy, especially in an older man
11. A hostile, blaming attitude toward authority figures
12. History of consulting physicians and being dissatisfied with them
13. Indication of paranoid thoughts

Similarly, Gorney uses two systems to identify potential problem patients. The first uses the acronym SIMON (single immature males, overly expectant, narcissistic) to describe certain traits to be wary of. The second method Gorney uses plots the patient's concern on one axis and the degree of deformity on the other. Patients with an appropriate amount of concern relative to their degree of deformity are excellent candidates for treatment. However, those with minimal deformity but disproportionate concern should be avoided, because frequently their expectations exceed the amount of aesthetic improvement that is possible. Furthermore, regardless of the degree of deformity, if the level of skill and expertise required to perform the rhinoplasty exceeds the surgeon's ability, the patient should be referred to a more proficient surgeon.

It should also be noted that men in general tend to have a poorer understanding of their deformity than women do. Furthermore, they tend to have a more difficult time elucidating the changes they want. Thus, for this subgroup of patients, during the initial consultation the physician must determine the patient's goals and whether they are realistic. A second follow-up consultation is recommended to reiterate the patient's desires, develop a realistic operative plan, and reaffirm the patient's understanding of the anticipated procedure.

Although there are different methods for integrating the patient into the surgical process, we find that computer imaging provides an excellent way for patients to gain a realistic understanding of the anticipated outcome. Although the images are not meant to guarantee surgical results, they do provide a visual level of understanding that may otherwise be lacking. These images, combined with standardized anterior, lateral, oblique, and basal photographs, serve as an integral element of the preoperative surgical plan.

Facial Analysis

Another critical element to proper preoperative surgical planning is critical facial analysis. Each individual nose has different proportions, morphology, and relative relationship with the surrounding face. To preserve nasofacial harmony, it is crucial to perform a systematic and meticulous analysis of the nose and face to accurately diagnose the deformity and then to determine the optimal surgical plan to correct the problem. It is also important to point out natural facial asymmetries to the patient preoperatively so the patient gains a better understanding of what was actually present before any operative intervention is performed.

We begin by evaluating the patient's skin type, thickness, and texture. As previously mentioned, this is important because thicker, more sebaceous skin tends to camouflage changes made to the underlying osteocartilaginous framework, whereas thinner skin tends to show even minor changes.

We then proceed with the remainder of the facial analysis. There are some proportions and relationships of facial structures that make up an "attractive" face. Although more proportions have been described, the following are some of the fundamental relationships that we routinely use in our preoperative evaluation of the rhinoplasty patient. We will describe these relationships briefly for white women and point out when the proportions differ between men and women.

We start by evaluating for disproportions and anomalies of the underlying facial skeleton, including the maxillomandibular relationship. To do this, we divide the face into thirds using horizontal lines adjacent to the hairline, brow (at the level of the supraorbital notch), nasal base, and menton. The upper third (between the hairline and the brow) is the least important as it is the most variable (depending on the hairstyle). The lower third of the face is then subdivided into thirds by visualizing a horizontal line between the oral commissures (stomion). The upper third of this subdivision lies between the nasal base and the oral commissures, and the lower two thirds between the commissures (stomion) and the menton. If there are significant deviations from this, the patient may have underlying craniofacial disproportion (i.e., vertical maxillary excess) that may need to be addressed in addition to rhinoplasty.

The nasal length (radix to tip, or RT) is verified against the stomion-to-menton distance (SM), which should be equal, as was described by Byrd and Hobar.

For future reference, a natural horizontal facial plane is determined by drawing a line perpendicular to a plumb line superimposed over the head in repose and the eyes in straightforward gaze. As the external auditory canal position may differ between patients, this line may or may not correspond to Frankfort's line.

The lip-chin relationship is assessed next. Byrd determines ideal chin projection by dropping a vertical line from a point one half the ideal nasal length tangential to the vermilion of the upper lip. The lower lip should be no more than 2 mm behind this line. The ideal chin position varies with gender, with the chin lying slightly posterior to the lower lip in women but equal to the lower lip in men. If there is a discrepancy in these relationships, orthodontics, orthognathic surgery, or a chin implant may be necessary to improve facial harmony.

Nasal deviation is noted by drawing a line from the midglabellar area to the menton, bisecting the nasal ridge, upper lip, and Cupid's bow. This line will pass between the central incisors in patients with normal occlusion. Any deviation of the nose from this line will likely require septal surgery.

The nasal dorsum is then assessed on frontal (anteroposterior) view. The curvilinear dorsal aesthetic lines are traced from where they originate at the supraorbital ridges, and then follow along the corrugators to converge at the medial canthal ligaments, from which they flare slightly at the keystone area. From this point, they track to the tip-defining points, slightly diverging from each other along the dorsum during their course. Ideally, the width of the dorsal aesthetic lines should match the width of either the tip defining points or the interphiltral distance. These lines may be ideal, narrow, wide, asymmetrical, or ill-defined.

The width of both the bony base and the alar base are then assessed. The width of the bony base should be 80% of the normal alar base width (which typically is equal to the intercanthal distance), or the width of the palpebral fissure. If the bony base is greater than 80% of the alar base width (assuming the alar base width is normal), it is likely that osteotomies will be required to narrow the bony vault. Although men tend to have a wider bony base than women, it is important not to narrow the dorsum too much in males, since this could feminize the nose.

The alar base is analyzed, as is the geometry of the alar rims. If the alar base width is greater than the intercanthal distance, it must be determined if this is the result of a narrow intercanthal distance, a true increased interalar width, or alar flaring. If the intercanthal distance is smaller than the width of the palpebral fissure, it is better to maintain a slightly wider alar base. If there is true increased interalar width, a nostril sill resection may be indicated. If the increase in width is secondary to alar flaring (greater than 2 to 3 mm outside the alar base), an alar base resection should be considered. Again, the alar rims should also be assessed for symmetry, and should flare slightly outward in the inferolateral direction.

While still addressing the frontal view, the surgeon assesses the tip to determine the supratip break, the tip-defining points, and the columellar-lobular angle. These points serve as landmarks to draw two equilateral triangles with their bases opposed. If these triangles are asymmetrical, the underlying reason should be investigated, and the patient will likely require tip modification.

The final assessment on frontal view is of the outline of the alar rims and the columella, which should resemble a seagull in gentle flight, with the columella lying just inferior to the alar rims. If the curve is too drastic, the patient probably has an increased infratip lobular height, which will need correction. If, on the other hand, the curve is flattened, the patient probably has decreased columellar show, which may require columellar augmentation or alar rim modification.

The basal view of the nose is addressed next, with the outline of the nasal base describing an equilateral triangle with a lobule-to-nostril ratio of 1:2. The nostril itself should have a teardrop-like geometry, with the long axis from the base to the apex oriented in a slight medial direction.

The lateral view is then analyzed, beginning with the position and depth of the nasal root at the radix. The nasofrontal angle connects the brow and the dorsum through a soft concave curve at the radix. The apex of this angle should lie between the upper lid eyelashes and the supratarsal fold, with the eyes in natural horizontal gaze. Although this angle can vary from 128 to 140 degrees, it is ideally 134 degrees in women and 130 degrees in men. Other important reference measurements from this view include the nasion-medial canthal distance, which should be approximately 15 mm, and the nasion-corneal plane distance, which is approximately 11 mm.

While still concentrating on the lateral view, it is important to remember that the perceived nasal length and tip projection can be altered by the position of the aforementioned nasofrontal angle. For instance, if the nasofrontal angle is positioned more anteriorly and superiorly than normal, the nose will appear elongated, the nasofacial angle will be decreased, and the tip projection will appear diminished (*yellow line*). Conversely, if the nasofrontal angle is too posteriorly and/or inferiorly positioned, the nose will appear shorter, and the tip more projecting (*red line*). Ideally, the nasofacial angle (as defined by the junction of the nasal dorsum with the vertical facial plane) should measure 32 to 37 degrees.

Tip projection is addressed next, still from the lateral view. Although several methods have been described to assess this, we prefer the following two ways. In a patient with normal upper lip projection, we begin by drawing a line from the alar-cheek junction to the tip of the nose. The tip projection is considered normal if 50% to 60% of the tip lies anterior to a vertical line adjacent to the most projecting part of the upper lip. The tip is considered to be overprojected if greater than 60% of the

tip lies anterior to this reference line and may therefore require deprojection. Conversely, if less than 50% of the tip lies anterior to the line, the projection may need to be augmented (in any number of ways).

The second method we use to help assess tip projection is by comparing it to the alar base width (they should be equal), and by comparing the ratio of nasal length (RT) to the tip projection (alar base to tip). In the latter, the ideal tip projection is $0.67 \times \text{RT}$.

After the tip projection is assessed, the dorsum is analyzed. The aesthetic nasal dorsum should lie approximately 2 mm behind and parallel to a line from the radix to the tip-defining points in women, but in men it should approach this line to avoid feminizing the nose.

The degree of supratip break is appraised when the nasal tip projection and dorsum are evaluated. A slight supratip break is preferred in women, but not in men. This gives the nose more definition and distinguishes the dorsum from the tip.

The nasolabial angle is used to determine the degree of tip rotation. This angle is obtained by measuring the angle between a line coursing through the most anterior and posterior edges of the nostril and a plumb line dropped perpendicular to the natural horizontal facial plane. This angle should be between 95 and 100 degrees in women and between 90 and 95 degrees in men.

The nasolabial angle should not be confused with the columellar-labial angle, which is formed at the junction of the columella with the upper lip–infratip lobule. Increased fullness in this area is usually caused by a prominent caudal septum and gives the illusion of increased rotation, even though the nasolabial angle is normal. This angle is normally 30 to 45 degrees.

The alar-columellar relationship is then assessed in the lateral and frontal views. A line is drawn through the long axis of the nostril, and a perpendicular line is drawn from alar rim to columellar rim that bisects this axis. The distance from the alar rim (point A) to the long axis line (point B) should equal the distance between the long axis line to the columellar rim (point C) if the alar-columellar relationship is normal ($AB = BC \approx 2 \text{ mm}$). If these measurements are not normal, the deformity can be categorized into six classes. Classes I to III describe increased columellar show, classes IV to VI demonstrate decreased columellar show (described later in the section on operative techniques). These may be treated differently depending on the class of deformity.

Again, these proportions generally apply to white women. Generally, the male face tends to have a squarer, less rounded appearance, with stronger, more pronounced features. The key differences in men are as follows:

The male dorsum tends to be straighter and wider, with decreased concavity at the superciliary ridges.

The male nasal dorsal profile should hug a line drawn from the radix to the tip-defining points instead of falling 2 mm behind and parallel to this line, as in women.

There should be no supratip break.

Tip rotation in men is slightly less than in women (90 to 95 degrees versus 95 to 100 degrees in women), because men have less nostril show as a result of a longer nasal dorsum.

Men have a stronger chin, abutting the plumb line drawn tangential to the upper lip; in women the chin is 2 to 3 mm posterior to this line.

In general, men have a broader, more bulbous nasal tip.

Male skin is usually thicker, masking the amount of perceivable change.

It is important to remember that these proportions are general guidelines and can vary tremendously between different individuals. In addition, it is important to consider the patient's ethnicity and culturally accepted aesthetic ideals as rhinoplasty is becoming increasingly more popular amongst different ethnic groups.

Rhinoplasty in Patients of African Descent

Compared with the nasal ideals for whites, the noses of patients of African heritage typically feature a wide, low nasal dorsum, decreased nasal length and tip projection, poor nasal tip definition, an acute columellar-labial angle, and alar flaring.

The goals of rhinoplasty in a patient of African descent include achieving a narrower, straight dorsum, improved tip projection and definition, decreasing alar flaring and alar base width. Improvement of the typically low nasal dorsum may require cartilage grafting. Tip definition is improved by suture techniques and cartilage grafting, as needed.

Rhinoplasty in Patients of Middle Eastern Descent

The complex nasal morphology of the Middle Eastern nose warrants discussion: it demonstrates a combination of features seen in individuals of African, Mediterranean, and Hispanic origin. The Middle Eastern nose features thick, sebaceous skin and is most prominent at the supratip. The radix may overproject, the bony and middle vaults tend to be wide, and a significant dorsal hump is common. The lower lateral cartilages can feature malposition of the lateral crura and weak middle and medial crura, resulting in various characteristic deformities of the tip, including poor tip definition, underprojection of the tip, or a droopy tip with an acute columellar-labial angle. The tip deformities may be exacerbated by hyperdynamic depressor septi nasi muscles. Nasal deviation and nostril asymmetry are also common.

Achieving ethnic nasofacial harmony in a Middle Eastern patient includes moderate dorsal hump reduction, narrowing of the wide nasal bones, debulking of soft tissue, particularly at the supratip, modest correction of underrotation and underprojection of the nasal tip, improvement of tip definition, repositioning of the alar bases, and correction of nostril asymmetries.

These guidelines are meant only as a systematic method of analysis with general proportions and relationships. Each nose should be individualized to the patient's facial structure and tempered by the patient's desires to create facial harmony and balance.

Intranasal Examination

The final part of the preoperative analysis of the rhinoplasty patient is the intranasal examination. This is performed with a nasal speculum, headlight, and vasoconstriction. The septum, turbinates, and external and internal nasal valves are evaluated for obvious deformities or pathology. Septal perforation or deviation should be identified. Septal deviation can involve deviation of the septal cartilage, perpendicular plate of the ethmoid bone, or vomer and can cause obstruction of one or both of the nasal airways, along with external deviation of the nose. Guyuron et al classified septal deviation as follows:

1. Septal tilt 40%
2. Anteroposterior C-shaped deviation 32%
3. Cephalocaudal C-shaped deviation 4%
4. Anteroposterior S-shaped deviation 9%
5. Cephalocaudal S-shaped deviation 1%
6. Localized deviation or septal spur 14%

Septal tilt is the most common type, where the quadrangular cartilage and perpendicular plate of the ethmoid are straight but the quadrangular cartilage is tilted to one side internally and to the opposite side externally. Hypertrophy of the inferior turbinate contralateral to the side of internal deviation is usually present.

If inferior turbinate hypertrophy is identified, the underlying cause should be investigated. Turbinate enlargement can be congenital or acquired. If acquired, it may be the result of autonomic, environmental, medical, or anatomic factors. A complete workup, especially a detailed history, is essential. The external nasal valve should be examined for patency on normal and forced inspiration. Collapse of the alar rim from weakness of the lower lateral crus should be evaluated. A Cottle test should be performed to assess the internal nasal valve. Septal deviation or midvault collapse can contribute to airway obstruction in this area. Finally, nasal polyps or masses may require further evaluation and treatment.

Preoperative Planning

After the initial history-taking and physical examination, the procedure is fully discussed with the patient. The risks and benefits of the procedure are detailed, and all questions are answered. The patient is provided with a written, detailed estimate of surgical charges with complete explanations by the practice's billing staff. We ask the patient to return for a second clinic visit to review the previous discussion and to assess the patient's psychological and emotional stability to ensure that he or she is a good surgical candidate. We also reiterate the deformities we plan to correct and answer any further questions. The consent form is reviewed again and signed. Our patients sign a form accepting financial responsibility. A preoperative instruction sheet and a list of medications to be avoided are also provided.

Preoperative Instructions

Two Weeks Before Surgery

1. Some medications can interfere with anesthesia and cause undesirable side effects that can affect your surgery. Please read over the enclosed medication information list and let us know if you take any of them. Aspirin should not be taken at least 2 weeks before or after surgery. Tylenol is a good medication to take for any aches or pains you may have before surgery.
2. Smoking will affect how you heal. It is very important to stop smoking 4 weeks before your surgery.
3. If you develop a cold, facial sore, or any other illness before surgery, please notify us.
4. If you are having surgery as an outpatient, please be certain that arrangements have been made for a responsible adult to drive you to the surgery center and pick you up after your surgery and to stay with you for the first 24 hours.

Evening Before Surgery

1. Shampoo your hair and wash your face. Do not use conditioner or hair spray after shampooing.
2. Make some Jell-O and/or soup for after surgery.
3. Get a good night's rest.
4. Do not eat or drink anything after midnight.

Morning of Surgery

1. Arrive at the surgery center/hospital by _____.
2. Do not eat or drink anything if your surgery is scheduled before noon. If your surgery is scheduled after noon, you may have coffee or tea and dry toast no later than 6 hours before your scheduled surgery time.
3. Do not wear wigs, hairpins, hairpieces, or jewelry. Dress in old, loose, comfortable clothes. Do not wear pullover tops or pantyhose. Wear slip-on shoes.
4. Have someone drive you to the surgery center and make certain a responsible adult will be available to take you home and stay with you for 24 hours. Put a pillow and blanket in the car for the trip home.

We convert our operative plan into a graphic representation (using Gunter Graphics) to assist us in the operating room. Any modifications to the plan are documented intraoperatively on a worksheet, transposed to the graphic depictions afterward, and placed in the patient's chart for future reference.

On the morning of surgery, any final questions are answered, and the patient is taken to the operating room and positioned supine on the operating table. Noninvasive hemodynamic monitoring devices are placed, and all pressure points are padded appropriately. One gram of cefazolin is administered intravenously for perioperative antibiotic prophylaxis. We prefer general anesthesia for our patients, although certainly local anesthesia with intravenous sedation may be used. After anesthetic is ad-

ministered, the nasal vibrissae are clipped and the nares are swabbed with povidone-iodine (Betadine) solution.

We mark a line for the anticipated incision (transcolumellar stairstep, if using an open approach) and then inject approximately 10 ml of 1% lidocaine with 1:100,000 epinephrine into the intranasal mucosa, along the septum, and into the soft tissue envelope. The inferior turbinates are injected if we anticipate performing an inferior turbinoplasty.

Location and Volume Distribution of 1% Lidocaine With 1:100,000 Epinephrine

Location	Amount (ml)
Vestibules/aperture	2
Dorsum	1
Lateral walls	2
Tip/columella	2
Distal septum	2
Inferior turbinates	1
TOTAL	10

After the local anesthetic is injected, the nasal mucosa is shrunk with cottonoid pledgets soaked in oxymetazoline. A drop of methylene blue is added to the oxymetazoline to differentiate this from the local anesthetic and prevent inadvertent injection. We do not use 4% cocaine, because comparable hemostasis can be obtained using lidocaine with oxymetazoline, avoiding the use of a controlled substance with potential cardiac effects that may be seen with cocaine, although certainly both have proved effective. A throat pack is placed in the oropharynx to prevent possible ingestion of blood during surgery, which could lead to postoperative nausea and vomiting. At this point the patient is prepared and draped for surgery.

Operative Technique

Incision: Endonasal Approach

When deciding on what incision to use in the endonasal approach, once again the surgeon must employ accurate preoperative nasofacial analysis. Because the objective is to minimize incisions, any incision that can be used to access multiple areas should be used so that separate incisions become unnecessary. For example, if an alar contour graft will be needed as well as rasping of a dorsal hump, the access incision can be made on the same side as the alar contour graft.

There are two basic techniques for access in endonasal rhinoplasty: nondelivery and delivery. The nondelivery approach can use either a transcartilaginous (cartilage-splitting) incision or a retrograde or eversion incision. The transcartilaginous incision is made several millimeters cephalad to the caudal margin of the lateral/middle crura, thus preserving a rim strip to support the ala. Double hook retraction combined with digital alar eversion provides the necessary exposure to facilitate this.

The vestibular skin is carefully dissected off the overlying cartilage to expose the cartilage for resection. In the retrograde approach, the vestibular incision is made at the most cephalic margin of the lower lateral cartilage rather than through it. Again, a double hook retractor and digital manipulation are used to facilitate exposure. The theoretical advantage to this incision is that it maintains the caudal alar margins and prevents potential scar contracture deformities in this area.

The delivery approach is used in cases in which moderate tip modifications are necessary, especially if the angle of divergence (as a measure of tip bifidity) is large. Again, using a double hook retractor in the ala and digital counterpressure to expose the cartilaginous margins, a No. 15 blade scalpel is used to create an intercartilaginous incision starting laterally just above the cephalic margin of the lateral crus. It is extended medially approximately 2 mm caudal and parallel to the limen vestibule. An infracartilaginous incision is then created along the caudal margin of the lower lateral cartilage (from lateral crus to medial crus), ending at the columellar-lobular junction. Sharp scissors are then used to dissect the soft tissue off the cartilage just above the perichondrium, including over the dorsal cartilaginous septum. The same incision is made on the contralateral side, and the two incisions are connected in the midline over the anterior septal angle, ending in a hemitransfixion incision. If necessary, this may be extended to a full (complete) transfixion incision. The lower lateral cartilage is then dissected free from the surrounding tissue and “delivered” outside the incision. If there is difficulty delivering the cartilages, the incisions may be extended and the soft tissue undermined to a greater extent. Once the cartilages (and domes) are delivered, modifications may be made.

55-1 Open approach
to primary
rhinoplasty

Incision: Open Approach

In the open approach, we use a stairstep transcolumellar incision across the narrowest portion of the columella with a No. 15 blade scalpel. The stairstep is important, because it helps to provide landmarks for accurate closure, prevents linear scar contracture, and camouflages the scar.

Bilateral infracartilaginous extensions are then performed. These begin first from lateral to medial along the caudal border of the lower lateral cartilage, then from medial to lateral, from the level of the transcolumellar incision to the apex of the middle crus, where it joins the lateral incision. A double-pronged skin hook placed along the alar rim is used to perform this maneuver. External digital pressure is used to evert the ala and augment visualization of the lateral crus.

Important points during this step are as follows:

- Take your time—most mistakes are made trying to obtain exposure.

- Keep the incisions superficial to prevent unnecessary injury to the underlying cartilages.

- Identify the caudal border of the lower lateral cartilage before cutting.

Skin Envelope Dissection

Dissection of the skin envelope should be done meticulously. As mentioned previously, it is important to perform the dissection in the supraprichondrial/submusculoaponeurotic plane, because this avoids injury to the arterial, venous, and lymphatic supply to the nose. There should be no residual soft tissue remaining on the lower lateral cartilages if the dissection is performed properly. This dissection is then continued in a superior direction, exposing the cartilaginous dorsum and ULCs. At the level of the bony pyramid, the scissors are traded for a Joseph periosteal elevator, which continues the dissection in a subperiosteal plane to the radix. It is im-

portant to limit the extent of the subperiosteal dissection to just the area of the bony dorsal hump that needs to be addressed; otherwise, all the periosteal attachments to the nasal bones may be disrupted, leading to prolonged wound healing and potential nasal bone malposition, especially after osteotomy.

Key points are as follows:

Take your time—it is easier to go slowly through the correct dissection than to spend more time fixing mistakes from inadvertent mishaps resulting from haste.

Stay just above the perichondrium in the submusculoaponeurotic plane.

Limit lateral subperiosteal dissection over the bony pyramid.

Make certain the ULCs are not detached from the nasal bones by accidental dissection under the nasal bones (rather than on top).

Nasal Dorsum

We prefer to perform component dorsal hump reduction of the osteocartilaginous hump instead of composite reduction because component reduction offers incremental control and greater precision. This process involves four basic steps, after the skin envelope dissection just described:

Separation of the ULCs from the septum

Incremental reduction of the septum proper

Incremental dorsal bony reduction (using a rasp)

Three-point palpation test

Separation of the Upper Lateral Cartilages From the Septum

To minimize mucosal trauma that could result in internal nasal valve stenosis or vestibular webbing, it is critical to create bilateral dorsal submucoperichondrial tunnels before embarking on reduction of the dorsal hump. This is done by elevating

the mucoperichondrium of the dorsal septum from caudal to cephalad with a Cottle elevator until the nasal bones are reached. The transverse processes of the ULCs are then sharply separated from the septum using a No. 15 blade scalpel without damaging the mucosa. If necessary, spreader grafts or dorsal grafts can then be placed in this enclosed space, separated from the nasal cavity (later in the case).

Incremental Component Cartilaginous Dorsal Septal Reduction

At this point, the cartilaginous dorsal septum is separated into three components: the septum centrally and the transverse portions of the ULC laterally. The cartilaginous septum is addressed by serially shaving down the dorsal hump deformity with a sharp scalpel under direct vision. This maneuver is done carefully, avoiding damage to the adjacent ULCs. If the septum and ULCs were taken down en bloc, not in component fashion, the patient will end up with a rounded dorsum. Furthermore, if the ULCs were resected to a greater extent relative to the septum, an inverted-V deformity will result. Although reduction of the ULCs is not routinely performed, it may be necessary in certain circumstances. If so, it must be done after the septal cartilaginous hump and bony dorsal hump are addressed. Again, overresection of the ULCs must be avoided to prevent internal nasal valve collapse and long-term dorsal irregularity. Maintaining the transverse portions of the ULC also preserves the dorsal aesthetic lines.

Component Bony Dorsum Reduction

The method of reducing the bony dorsum depends on the amount of deformity that requires resection. Large humps (generally greater than 5 mm) are reduced either by a power burr with a dorsal skin protector or a guarded 8 mm osteotome. For humps smaller than 5 mm, a sharp rasp is used (we prefer a down-biting diamond rasp). When rasping, it is important to maintain a slightly oblique bias to minimize potential mechanical avulsion of the ULCs from the nasal bones. The rasping is done in a controlled, methodical fashion, proceeding along the left and right dorsal aesthetic lines, and then centrally. The nondominant thumb and index finger are used simultaneously for maximum control.

Three-Point Dorsal Palpation Test

The three-point dorsal palpation test is performed repeatedly throughout the component dorsal hump reduction process, after redraping the skin envelope. This test is performed with a saline-moistened dominant index fingertip, which is used to gently palpate the left and right dorsal aesthetic lines, as well as centrally, to detect any dorsal irregularities or contour depressions.

Septal Reconstruction/Cartilage Graft Harvest

If the septum is deformed, or if cartilage is needed for graft construction, the septum is harvested. The septum is ideal for cartilage graft harvest in rhinoplasty because of its close proximity to the operating field and its minimal donor site morbidity. In the endonasal approach, a Killian or hemitransfixion incision is generally used because a full transfixion incision can lead to decreased tip projection, especially if dissected down over the anterior nasal spine.

In the open approach, the cartilage harvest is begun by separating the middle crura, incising the interdomal suspensory ligament, and exposing the anterior septal angle. A No. 15 blade scalpel is used to incise the septal perichondrium, exposing the distinct bluish-gray underlying cartilage (1). A Cottle elevator is used to create a submucoperichondrial plane posteriorly to the perpendicular plate of the ethmoid (2) down to the nasal floor (3) and across the face of the septum (4).

If the dissection is difficult at first, it may be because the improper plane has been accessed, and a deeper plane should be sought. The dissection should be more difficult at the junction of the cartilaginous and bony septum, and therefore one should proceed with caution in this area because perforation of the overlying mucoperichondrium is more likely. It may be advantageous to dissect two separate tunnels, one subperichondrial and one subperiosteal, and then divide the junction sharply to help avoid potential perforation in this area. The same dissection is then performed on the contralateral side. After this is complete, a Vienna speculum is used to directly visualize both sides of the septum to identify underlying deformity and to help achieve exposure for the septal harvest.

When harvesting septal cartilage, it is necessary to preserve an L-strut with 10 mm of dorsal septum and 10 mm of caudal septum retained to support the lower nasal vault. After the cartilage is resected, it is preserved in saline solution. Any residual deviations in the ethmoid or vomer are rongeured or resected, and any mucosal perforations are repaired.

Correction of the Deviated Nose

Septal deviation, described previously in this chapter, can manifest as external deviation of the nose. We classify the deviated nose into three basic types: caudal septal deviations, concave dorsal deformities, and concave/convex dorsal deformities.

Classification of the Deviated Nose

Type I: Caudal septal deviation

- a. Straight septal tilt
- b. Concave deformity (C-shaped)
- c. S-shaped deformity

Type II: Concave dorsal deformity

- a. C-shaped dorsal deformity
- b. Reverse C-shaped dorsal deformity

Type III: Concave/convex dorsal deformity (S-shaped)

Correction of the deviated nose is based on the following principles:

1. The open approach to expose all deviated structures
2. Release of all mucoperichondrial attachments to the septum, especially the deviated part
3. Straightening of the entire septum while maintaining a 10 mm caudal and dorsal L-strut
4. Restoration of long-term support with buttressing caudal septal batten or dorsal spreader grafts
5. Outfracture or submucous resection of hypertrophied anteroinferior turbinates, if necessary, for correction of the deviated septum
6. Precisely planned and executed external percutaneous osteotomies

Inferior Turbinoplasty

In patients with symptomatic nasal airway obstruction caused by inferior turbinate hypertrophy that is refractory to medical management, an inferior turbinoplasty is performed. This can be done by turbinate outfracture, submucous morselization of the turbinate bone, or submucous resection of the anterior one third to one half of the inferior turbinate. The submucous resection is done by developing medial mucoperiosteal flaps, exposing the conchal bone using a Cottle elevator, and sharply resecting the proper amount. The flaps are replaced after this resection without the need for suture repair. It is important to note that the extent of the conchal bone resection is limited to the anterior portion. This is done mainly to avoid complications of bleeding if the posterior portion is resected.

Cephalic Trim

In cases in which the tip is boxy or bulbous and requires better refinement and definition, when the tip-defining points need medialization, or when rotation of the tip is desired, a cephalic trim is performed. This is done by using a caliper to measure along the caudal margin of the lower lateral cartilage to preserve a 6 mm rim strip. After this is demarcated, the cephalic portion of the middle and lateral crura is resected. The cartilage is preserved for possible use later in the case.

Lower Lateral Crural Turnover Flap

A lower lateral crural turnover flap is another useful technique to address paradoxical fullness while providing additional support to the lower lateral cartilages. It is beneficial for deformities, weakness, and collapse of the lower lateral crura and can also be used to improve lower lateral crural strength during tip reshaping. However, there must be sufficient lower lateral crura to leave a 6 mm rim strip. It can be used in combination with other external valve and alar arch supporting techniques.

A horizontal line that bisects the cephalic aspect of the lower lateral crus from the 6 mm rim strip is marked with methylene blue. The cephalic aspect is dissected from the underlying vestibular skin inferiorly to this horizontal line and then the line is scored with a No. 15 blade and 2 mm full-thickness cuts at the medial and lateral ends of the horizontal line are performed. The flap is turned over and its caudal edge is secured with multiple horizontal mattress sutures.

Autospreader Flaps

Reduction of the nasal dorsum may compromise the internal nasal valves. Even a slight decrease in the angle between the upper lateral cartilage and the septum can lead to a significant increase in nasal airway resistance. Patients who have a high, narrow dorsum, a weak middle vault, short nasal bones, or a positive Cottle test preoperatively are at risk for developing postoperative internal nasal valve dysfunction and consequently, nasal airway obstruction.

In these cases, the use of autospreader flaps fashioned from the dorsal aspects of the upper lateral cartilages can maintain patency of the internal nasal valves while preserving the dorsal aesthetic lines. After component dorsal hump reduction has been performed, the overprojecting dorsal aspect of the upper lateral cartilages is incised, leaving the underlying mucoperichondrium intact. This dorsal portion of the upper lateral cartilage is then rotated internally approximately 90 degrees to lie between the septum and the medial edge of the upper lateral cartilages supported as a flap by its attachment to the mucoperichondrium. The new dorsal edges of the upper lateral cartilages are then sutured with 5-0 PDS at the midline to the rotated autospreader flaps and secured along the septum.

Limitations using this technique include patients with a deviated dorsal septum or asymmetrical dorsal aesthetic lines, a weak bony vault or lower lateral cartilages, a deviated nasal tip, or lack of tip support. Spreader grafts are indicated in these cases.

Spreader Grafts

Spreader grafts can be used to help stent open the internal valve, stabilize the septum, and preserve the dorsal aesthetic lines. These grafts usually are obtained from septal cartilage and are designed to measure approximately 25 to 30 mm by 3 mm. Their cephalic ends can be trimmed obliquely to fit snugly underneath the bony dorsum and their caudal ends can be placed either at the septal angle (if lengthening of the nose is not desired) or extending past it (if lengthening is desired). Furthermore, the grafts can be placed in a visible position (secured in a higher position along the septum) or in an invisible position (positioned lower). We secure the grafts with 5-0 PDS in horizontal mattress fashion.

Tip Modification

Altering Tip Projection

It is important to recognize the factors that contribute to tip projection in situ before embarking on a discussion on how to precisely alter tip projection. There are six key anatomic elements to tip projection:

1. The supporting ligament between the anterior septal angle and the overlying dermis
2. The length and strength of the lower lateral cartilages
3. The suspensory ligament bridging the anterior septal angle
4. The fibrous connections between the upper and lower lateral cartilages (and septum)
5. The abutment of the cartilages with the piriform aperture
6. The anterior septal angle

Alteration of any of these anatomic structures can result in incremental changes in tip projection.

A graduated approach to tip projection is predicated on precise, incremental, non-destructive changes made to the tip complex, beginning with placement of a columellar strut graft, proceeding with suture modification, and finishing with the use of tip grafts.

The algorithm begins with placement of a columellar strut graft. This strut is usually fashioned from septal cartilage, and measures approximately 25 by 4 mm. It can be placed in a “fixed” (secured to the anterior maxilla) or a “floating” (not secured to the maxilla) fashion. This strut not only controls the columellar profile, but also bolsters tip projection and unifies the tip complex. The strut is placed by dissecting a pocket between the medial crura. A double-pronged hook is then used to gently retract the middle crura anteriorly to set the desired projection and symmetry. The strut is positioned in the pocket, and a 25-gauge needle is used to stabilize this configuration. Most are left floating on a soft tissue pad between the base of the pocket and the nasal spine. Medial crural sutures (described previously) are placed in horizontal mattress fashion to secure the complex. Further medial crural sutures can be placed more caudally on the medial crura to control flaring, if necessary.

The next step in altering tip projection involves suture techniques, which can increase tip projection by 1 to 2 mm. Suture techniques are ideal for controlling cartilage in a precise, nondestructive fashion. Although the choice of a particular suture material is surgeon dependent, the underlying premise is to choose a material that one can easily work with that will hold the cartilage in its altered position long enough to allow the natural fibrotic reaction to solidify the result. Although many suture techniques can be performed in both open and closed rhinoplasty (with cartilage delivery), we find

them easier to place using the open method, because it affords greater visualization and ease of placement. We commonly use four suture techniques to alter projection and shape the nasal tip:

1. Medial crural
2. Medial crural septal
3. Interdomal
4. Transdomal

Medial crural sutures serve to unify the medial crura of the lower lateral cartilages and are frequently used in conjunction with a columellar strut (to help stabilize the strut). They can also be used to straighten out flaring of the medial/middle crura (either on the caudalmost aspect or near the domal area), thereby effecting an increase in projection, albeit to a limited degree. We generally use 5-0 PDS suture in horizontal mattress fashion for this technique; however, the suture choice can vary by individual preference.

Medial crural septal sutures anchor the medial crura to the caudal septum, and can alter projection as well as rotation. They are often used in conjunction with columellar struts. We frequently use 5-0 clear nylon suture in spanning fashion for this technique.

Interdomal sutures are placed through the medial walls of the domes in mattress fashion and are tied to narrow the interdomal distance. This results in both an increase in tip refinement and an increase in projection.

Transdomal sutures are placed across the dome of the middle crura in mattress fashion so that the vestibular skin is not perforated. Local anesthetic can be used to hydrodissect a plane between the cartilaginous dome and the adherent underlying mucoperichondrium to help prevent inadvertent incorporation into the suture bite. We generally use 5-0 PDS in horizontal mattress fashion and leave the knots on the medial aspect of the dome. These sutures can be made asymmetrical to correct anatomic asymmetries, if necessary. They can be fashioned with one end left long on each side, and then subsequently tied together in a spanning configuration (resembling an interdomal suture) to narrow the tip-defining points. It is important, however, to prevent overtightening of this suture, which can result in an unnaturally sharp tip-defining point.

If more tip projection or definition is desired after the preceding maneuvers, tip grafts may be used. We find it easier to place these grafts using the open approach, because it allows excellent visualization, precise placement, and facilitates subsequent manipulation, if necessary. It should be noted that grafts, in general, have a tendency to be visible, so their use is reserved only for the patient in whom the prior, more predictable methods do not result in satisfactory tip projection. There are three general types of tip grafts:

1. Onlay tip grafts
2. Infratip lobular graft
3. Anatomic tip graft

The onlay tip graft can be fashioned from any type of cartilage, although we find that the cartilage obtained from the cephalic trim harvest works exceptionally well. This graft is placed in a position overlying the dome of the middle/lateral crura and fixed in place using the techniques just described. We generally use 5-0 PDS suture for this, with the knots hidden underneath the dome.

The infratip lobular graft is positioned with its superior margin overlying the dome and tip-defining points and extending inferiorly a variable distance, usually 10 to 12 mm. It is usually shield-shaped, and has rounded graft edges to avoid a visible and palpable step-off. This graft increases infratip lobular definition and projection, and is secured in the same fashion as described previously.

The anatomic tip graft is a more aggressive type of graft that we generally use in difficult primary rhinoplasties, thick-skinned patients, and secondary rhinoplasties with inadequate tip projection. Its superiormost aspect is anchored to the ULCs and its inferiormost aspect secured to the caudal margin of the medial crura. It is essentially a combination graft and can be visible, so it must be placed carefully.

When trying to *decrease* nasal tip projection, once again it is important to realize the anatomic factors that contribute to tip projection in the first place. If the support derived from the fibroelastic and ligamentous attachments is disrupted, tip projection becomes primarily dependent on the length and strength of the lower lateral cartilages. Therefore, in the open approach, if the skin envelope has been undermined and these fibroelastic tissues have been severed, the primary means of decreasing tip projection lies in altering these lower lateral cartilages. This may include techniques such as transection, setback, and resuturing of the medial or lateral crura. It is important to recognize that if the tip projection is decreased significantly, alar flaring or columellar bowing may result, which would necessitate concomitant correction.

Altering Tip Rotation

Using the nasofacial analysis techniques described, rotation is evaluated generally by the nasolabial angle. This angle, found by measuring the angle between a line coursing through the most anterior and posterior edges of the nostril and a plumb line dropped perpendicular to the natural horizontal facial plane, should be between 95 and 100 degrees in women and between 90 and 95 degrees in men.

When changing tip rotation, the extrinsic forces holding the tip at its current angle must be released. This is generally done by severing the connection between the lower and upper lateral cartilages. This frequently takes the form of a cephalic trim, as described previously. Furthermore, the fibrous attachments of the medial crura and the caudal septum can be transected to release tension on the nasal tip and allow for more cephalad rotation. This is generally achieved by resecting a variable amount of the caudal septum. This maneuver can also affect tip projection.

Depending on the amount of tip rotation, it may be necessary to perform a limited resection of the nasal mucosa and membranous septum to maintain proper nasal balance and harmony. After the tip is rotated, its position is maintained with suture techniques (medial crural septal sutures) and/or a columellar strut or septal extension graft.

Alar Rims

Alar Contour Grafts

Alar contour grafts are used as a simple and effective method to correct and prevent alar notching or retraction, and facets of the soft tissue triangles. A subcutaneous pocket below the infracartilaginous incision and parallel to the alar rim is created with dissection scissors. The pocket should span the length of the deformity and extend 3 mm to each side of it. An alar contour graft is typically 4 by 10 mm, but it may be need to be larger, depending on the size of the deformity.

Lateral Crural Strut Grafts

Lateral crural strut grafts are used to support weak lateral crura, prevent collapse of the external nasal valve, address malposition of the lateral crura, or increase tip projection. The vestibular skin is dissected from the deep surface of the posterior two thirds of the lateral crus. The lateral crus is separated from the accessory cartilages.

A subcutaneous pocket below and adjacent to the accessory cartilages is dissected posteriorly to the piriform aperture. To correct malposition of the lateral crura, the pocket is dissected below the infracartilaginous incision and parallel to the alar rim. A 4 by 25 mm lateral crural strut graft is placed in the pocket and rests on the piriform aperture posteriorly. The anterior aspect of the graft is placed deep to the lateral crus and secured with two or three 5-0 PDS simple interrupted sutures.

Correcting the Alar-Columellar Relationship

Class I Deformity

When the patient has a class I deformity, or when the long axis–columellar rim distance (BC) is greater than 2 mm and the alar rim–long axis distance (AB) is normal, this is an example of a true hanging columella. Correcting this involves resecting either the caudal septum, the caudal portion of the medial crus, the caudal portion of the middle crus, or a combination of these, whichever is responsible for the deformity.

Class II Deformity

A class II deformity, or a retracted ala (AB greater than 2 mm, BC less than 2 mm), is treated in several ways. One method is to insert an elliptically shaped composite graft from an access incision made in the vestibular skin. The graft is made slightly larger than is needed to compensate for secondary contraction. If the retraction is mild and there is no tissue deficiency present, an alternative technique can be used where the lateral crura are detached from the accessory chain and repositioned inferiorly. A final method is to place an alar contour graft (nonanatomic position) in a pocket created along the vestibular rim to displace the ala inferiorly.

Class III Deformity

A class III deformity is a combination of a class I and class II deformity and is therefore corrected with a combination of the two procedures.

Class IV Deformity

A class IV deformity is a hanging ala (AB less than 1 mm, BC less than 2 mm). This is usually treated with an elliptical excision of vestibular skin. Care is taken to avoid overresection of skin in this maneuver, because an abnormal, rolled-in appearance of the alar rim can result.

Class V Deformity

A class V deformity is a retracted columella (AB less than 2 mm, BC less than 1 mm). The treatment of choice for this deformity is placement of a columellar strut, which is positioned more caudally to extend the caudal dimension of the columella.

Class VI Deformity

A class VI deformity is a combination of class IV and class V and is treated with a combination of the techniques just described.

Osteotomies

Osteotomies are a powerful technique in rhinoplasty. The indications to perform osteotomies, regardless of technique, are as follows:

- To narrow the lateral walls of the nose
- To close an open-roof deformity (after dorsal hump reduction)
- To create symmetry by straightening the nasal bony framework

Contraindications to osteotomies can include patients with short nasal bones; elderly patients with thin, fragile nasal bones; and patients with heavy eyeglasses. There are several osteotomy techniques, including medial, lateral, transverse, or a combination of these. Furthermore, they can be performed through either an external or internal approach.

A lateral osteotomy may be performed as *low-to-high*, *low-to-low*, or *double-level*. They may be combined with medial, transverse, or greenstick fractures of the upper bony segment, as well. No matter how the osteotomy is performed, however, it is necessary to preserve Webster's triangle, which is an area of the caudal aspect of the maxillary frontal process that is near the anterior aspect of the inferior turbinate. By preserving this area, patency of the internal valve is preserved during osteotomies, and functional nasal airway obstruction from collapse is prevented. Furthermore, regardless of the technique used in performing the lateral osteotomy, it is important to maintain a smooth fracture line by staying low along the bony vault, thereby preventing the potential for a step-off deformity. The cephalic margin of the osteotomy should not be higher than the intercanthal line (the level of the medial canthi); the thick nasal bones above this level increase the technical difficulty, and it is possible to cause iatrogenic injury to the lacrimal system (with resultant epiphora).

A low-to-high osteotomy is generally used to correct a small open roof deformity or to mobilize a medium-wide nasal base. It begins low at the piriform aperture and ends high medially on the dorsum. The nasal bones are then "greensticked" to medialize them, with predictable fracture patterns obtained based on nasal bone thick-

ness. Occasionally, a separate superior oblique osteotomy is necessary to mobilize thicker nasal bones enough to be greensticked. A low-to-low osteotomy is generally a more powerful technique, in that it results in more medial movement of the nasal bones, and therefore is classically used when there is a large open-roof deformity or if a wide bony base requires correction. It starts low along the piriform aperture and continues low along the base of the bony vault to end in a lateral position along the dorsum near the intercanthal line. As there is more bone between the cephalic aspect of this osteotomy and the midline, this type of osteotomy technique is frequently accompanied by a medial osteotomy to better mobilize the nasal bones to achieve the desired result.

We have refined our preferred technique of external perforated lateral osteotomies, which has proved to be well controlled, predictable, and reproducible. Furthermore, there are certain unique advantages to this technique based on the preservation of the periosteal attachments, namely:

- Decreased amount of dead space
- Reduced subluxation and subsequent airway compromise
- Greater overall stability after positioning

Our technique is as follows:

1. Inject both intranasally and along the lateral nasal sidewalls with 2 ml of 1% lidocaine with 1:100,000 epinephrine, allowing 5 to 7 minutes for the hemostatic process to take effect.
2. Introduce a sharp 2 mm osteotome percutaneously on the midportion of the bony nasal pyramid at the level of the inferior orbital rim and nasofacial junction. It must be held at a plane parallel to the surface of the maxilla.
3. To avoid injury to the angular artery, sweep the osteotome down the lateral nasal sidewall in a subperiosteal plane.

4. Position the osteotome at an angle such that one edge is in contact with the bone and strike with the mallet. The endpoints are a change in the feel and sound at that location.

5. Extend the osteotomy in an inferior, superior, and superior-oblique manner at the level of the piriform. Leave a 2 mm gap between each individual osteotomy.
6. Perform the same procedure on the contralateral nasal wall.
7. After the osteotomies are completed, use gentle pressure between the thumb and forefinger to perform a greenstick fracture of the nasal bones to position them in the desired location.

8. Cover with flesh-colored Steri-Strips and apply a dorsal compression splint (Denver splint), which is kept in place for 7 days to minimize postoperative edema.

Medial osteotomies are used to facilitate medial positioning of the nasal bones. They are generally indicated in patients with thick nasal bones or a wide bony base to achieve a more predictable result, because greenstick fractures in these subgroups can sometimes be difficult and can lead to unpredictable fracture patterns. Medial osteotomies can be used in conjunction with lateral osteotomies; however, it is not necessary to use both types in all cases. When using both techniques, the medial osteotomy is usually performed first, because this makes it technically easier to perform subsequent lateral osteotomies. Although the cant of the medial osteotomy can be varied (such as medial oblique, paramedian, or transverse), for the reasons just stated, the cephalic margin should not cross the intercanthal line.

It is paramount to avoid placing the medial osteotomy too far centrally as it connects with the lateral osteotomy because this can cause a *rocker deformity* in which the upper portion of the fractured nasal bone “kicks out,” resulting in a widened upper dorsum. This can be avoided by following an oblique angle. After the medial and lateral osteotomies are created, the nasal bones are greensticked, as described earlier, to the desired position.

Occasionally, a double-level lateral osteotomy is needed to correct lateral wall convexities that are too great to be corrected with a standard single-level lateral osteotomy, or when significant lateral nasal wall asymmetries exist. This is done by first making the upper (more medial) lateral osteotomy along the nasomaxillary suture line. The lower (more lateral) of the two is then created in standard low-to-low fashion.

Regardless of the operative technique, there are potential complications associated with osteotomies.

Potential Complications of Lateral Nasal Osteotomies		
Infections	Operative Trauma	Cosmetic Problems
Local	Hemorrhage (hematoma, ecchymosis)	Excessive narrowing or convexity
Abscess	Edema	Insufficient mobilization of lateral bony walls
Cellulitis	Nasal cyst formation	Unstable bony pyramid
Granuloma	Anosmia	Rocker deformity
Systemic	Arteriovenous fistula	Redundant soft tissue
Intracranial	Epiphora	Stairstep deformity
	Canalicular bleeding	Nasal bone asymmetry
	Neuromuscular injury	
	Intracranial injury	

Closure

After excellent hemostasis is achieved and the wound is irrigated to remove any excess debris, the skin envelope is redraped. If the patient has thick skin, and especially if the patient is a woman, we may choose to place a single 5-0 Vicryl suture from the dermis (underside of the skin envelope) to the underlying cartilaginous framework in an attempt to recreate a supratip break.

The transcolumnellar incision is then closed using 6-0 nylon suture in simple interrupted fashion, making sure the coaptation of the incision margins is precise. The stairstepping of the original incision helps us close this accurately. The infracartilaginous incisions are reapproximated using 5-0 chromic suture in simple interrupted fashion. We take special care to prevent overbiting with the suture, which can create contour irregularities and notching, especially in the soft triangle area.

If septal work has been performed, we place intranasal Silastic splints coated with antistaphylococcal antibiotic ointment. These are secured with a transseptal 3-0 nylon suture. The nasal dorsum is then carefully taped, and a malleable metal splint is applied over the dorsum. A drip pad is fashioned from a 2 by 2 gauze and secured under the nose with 1/2-inch paper tape. The throat pack is removed, and the oropharynx and stomach are carefully suctioned to help evacuate any blood that may result in postoperative nausea and vomiting.

Alar Base Surgery

In cases in which alar base surgery is necessary, it is generally performed after closure of the transcolumnellar and infracartilaginous incisions, but before intranasal and external splints are placed.

Analysis of the alar base was discussed earlier in the chapter. Based on proper and precise nasofacial analysis, alar base abnormalities may be diagnosed, which may

include wide or excessive nostril sills, a wide alar base, asymmetrical or malpositioned alar bases, or any combination of these.

Wide nostril sills, or alar flaring, is a relatively common problem. It is corrected by performing a small crescentic resection of the alar base, making sure to avoid extending the incision into the actual vestibule. The incision is placed approximately 1 to 2 mm above the true alar base to prevent alar notching. The soft tissue at the base is mobilized with judicious use of electrocautery and then transposed medially to the desired aesthetic endpoint, where it is sutured in place. We suture using the “halving principle” in this region, because the interior incision is shorter than the exterior incision.

A wide alar base is corrected in a similar fashion; however, the crescentic excision assumes a more wedge-type geometry and may include a small portion of the nostril sill. If a transcolumellar incision was used at the start, it is crucial that the alar base excision stay within 3 mm of the lateral alar groove, because the blood supply to the nasal tip can be jeopardized if the lateral nasal artery is inadvertently injured.

Although some have advocated suture techniques for narrowing the nasal base, we generally perform this with excisional techniques, as just described.

Depressor Septi Translocation

In patients who have a tension tip on animation (foreshortened upper lip with decreased tip projection), translocation of the depressor septi muscles is indicated. This is done in the following fashion.

An 8 to 10 mm transverse incision is made using electrocautery centered on the frenulum.

The inferior attachments of the depressor septi muscles are identified and dissected using electrocautery.

The depressor septi muscles are released from either the orbicularis or the periosteum (anatomy dependent).

The muscles are transposed and their ends sutured together using 4-0 chromic gut suture. The transverse incision is closed vertically to lengthen the upper lip.

Postoperative Management

All preoperative and postoperative instructions are given to the patients in writing before as well as on the day of surgery. Postoperatively, we routinely prescribe the following:

- Medrol Dosepak for 7 days (to minimize postoperative edema)
- Hydrocodone/acetaminophen 5:500 for postoperative pain every 4 to 6 hours as needed
- Normal nasal saline solution for postoperative nasal congestion
- Antibacterial ointment to incisions three times daily

The patient is instructed to keep the head of the bed elevated at an angle of 45 degrees beginning immediately after surgery to help minimize postoperative swelling. Cool compresses (Swiss Therapy eye masks) are used periorbitally during the day for the first 48 hours. Antibacterial ointment is applied three times daily to the incisions after gentle cleaning with a half-strength hydrogen peroxide–saline solution. The patient is instructed to change the drip pad under the nose as necessary until the drainage stops, at which time the pad and tape can be discontinued. Any manipulation of the nose, including rubbing, blotting, or blowing, is discouraged for the first 3 weeks postoperatively. Sneezing should be done through the mouth during this time. It is imperative to keep the nasal splint dry, and the patient's hair should be washed as in a beauty salon, with the patient leaning the head backward over the sink.

We maintain our patients on a liquid diet on the day of surgery, which is subsequently advanced the following day to a soft regular diet. Any foods that require excessive lip movements, such as eating apples or corn on the cob, should be avoided for 2 weeks after surgery.

During the first 2 weeks, nasal congestion may be minimized by the use of normal saline nasal spray and over-the-counter nasal decongestant sprays such as Afrin (oxymetazoline). However, the use of Afrin should be limited, because cessation can cause rebound nasal congestion. If patients have difficulty with the passage of air through the intranasal splints, they are encouraged to breathe through the mouth. If the patient is very congested, in-office suctioning may be warranted.

We ask the patient to return on postoperative day 5 to 7, at which time the sutures and nasal splints are removed. The nose (especially the tip) may appear swollen and turned up, and the tip may feel numb, but the patient is reassured that this is to be expected and will resolve with time, with normal sensation returning within 3 to 6 months. The patient cannot let anything, including eyeglasses, rest on the nose for

at least 4 weeks. Glasses should be taped to the forehead. Contacts can be worn as soon as the swelling has diminished enough to allow easy insertion (usually less than 5 to 7 days postoperatively). Patients are instructed to avoid direct sunlight and to wear sunscreen of SPF 30 or higher to prevent possible hyperpigmentation of the scar.

We ask our patients to restrict strenuous activity that increases their heart rate (above 100 beats/min) or blood pressure for 3 weeks after surgery. After that, they can gradually resume normal activity. Obviously, any contact sports or activities that may cause direct trauma to the nose are prohibited for at least 4 weeks after surgery. Although some patients' noses look excellent within 6 to 8 weeks, some may remain swollen for up to 1 year, but after 3 to 4 weeks such swelling will generally not be obvious to anyone but the patient.

After the first postoperative visit (within the first week), we ask the patient to return to the clinic at 3 and 8 weeks after the operation. We continue to follow the patient 3, 6, and 12 months after surgery, and then annually thereafter.

Outcomes

Although it is difficult to determine an exact revision rate following primary rhinoplasty, a recent survey of plastic surgeons and otolaryngologists revealed that 58% of those surveyed cited their revision rate less than 5%. This survey also revealed that the open approach was preferred by 73% compared with 20% preferring the closed approach for revision rhinoplasty.

In the senior author's (R.J.R.) practice, approximately 1 in 25 primary rhinoplasty patients requires revision. The most frequent reasons for reoperation include further tip refinement or correction of tip asymmetries (lower third), parrot beak or pinched supratip deformity (middle third), and excessive dorsal reduction or dorsal irregularities (upper third).

Functionally, continued nasal airway obstruction after primary rhinoplasty has, in our experience, usually been from excessive narrowing of the internal valve (without placement of spreader grafts). We used to see this more frequently when we performed more aggressive resection of the transverse processes of the ULCs. Once we adopted the component dorsal hump reduction technique with preservation of the ULCs, the incidence of internal valve obstruction decreased and the need for spreader grafts greatly diminished.

Results

Patient Example 1

This healthy 24-year-old woman presented for cosmetic rhinoplasty without nasal airway obstruction. She was unhappy with the appearance of her boxy tip and desired correction. The frontal view demonstrates adequate dorsal aesthetic lines, but asymmetrical fullness of her supratip. Her left lower lateral cartilage segment is more obliquely rotated than the right lower lateral cartilage. She has excess lateral alar convexity with preoperative alar notching.

Operative Goals

1. Drastically refine tip and narrow tip-defining points
2. Correct lateral alar convexity and alar notching

Surgical Plan

1. Open approach with transcolumellar stairstep incision connected to bilateral infracartilaginous incisions
2. Cephalic trim of lateral and middle crura leaving a 6 mm rim strip
3. Medial crural, interdomal and transdomal suturing
4. Bilateral alar contour grafts to correct lateral alar convexity and prevent alar notching

Preoperative and 15-month postoperative views demonstrate improvement of dorsal aesthetic lines and correction of her boxy tip. She has dramatic tip refinement, with reduction of supratip fullness and narrowed tip-defining points. Placement of alar contour grafts has corrected the lateral alar convexity and prevented alar notching.

Patient Example 2

This healthy 24-year-old woman had aesthetic as well as functional concerns. Aesthetically, she did not like her dorsal nasal contour and boxy, asymmetrical nasal tip. Functionally, she complained of left nasal airway obstruction. The lateral view demonstrates a slight dorsal hump, supratip fullness, decreased tip projection, and a columellar-labial angle of 100 degrees. Her basal view confirms an asymmetrical tip with left-sided alar collapse. The left lower lateral cartilage is concave; the right is convex. Her intranasal examination revealed left-sided deflection of the caudal septum.

Operative Goals

1. Remove small dorsal hump
2. Decrease tip rotation
3. Correct tip asymmetry
4. Refine the tip and reestablish tip-defining points
5. Correct left external nasal valve collapse and concave left lower lateral cartilage
6. Prevent postoperative alar retraction

Surgical Plan

1. Open approach with transcolumellar stairstep incision connected to bilateral infracartilaginous incisions
2. Component reduction of dorsum (2 mm)
3. Caudal septal resection with medial crural set-back sutures to decrease tip rotation
4. Septal cartilage harvest leaving a 10 mm L-strut
5. Left lower lateral crural turnover flap to correct concave left lower lateral cartilage
6. Right cephalic trim leaving a 6 mm rim strip
7. Bilateral spreader grafts
8. Medial crural, interdomal, and transdomal suturing
9. Columellar strut
10. Lateral osteotomies (external perforated)
11. Bilateral alar contour grafts to prevent alar retraction

Comparison of the patient's preoperative and 12-month postoperative appearance demonstrates a straight dorsum and a unified tip complex with correction of her tip asymmetry. The lateral view confirms the straight dorsal profile with a supratip break, normal tip projection, and a nasolabial angle of 95 degrees. There is an improved alar-columellar relationship. The basal view confirms correction of her tip asymmetry and shows restoration of the columellar-infratip lobular relationship. The left-sided external valve collapse was corrected with the lower lateral crural turnover flap while alar contour grafts were placed to prevent postoperative alar retraction.

Patient Example 3

This healthy 35-year-old man presented with a history of traumatic nasal airway obstruction, greater on the left than on the right. He was also concerned about a pinched appearance to his nasal tip and deviation of his nose to the left. The frontal view demonstrates obvious leftward septal deviation with deviated dorsal aesthetic lines. He has a wide bony base, an asymmetrical tip with a concave, pinched appearance and narrowed tip-defining points. His lateral view demonstrates mild dorsal hump with a low radix but adequate tip projection. His basal view corroborates the pinched tip deformity and a wide alar base. Intranasal examination revealed a septal tilt, with left septal deviation.

Operative Goals

1. Correct nasal airway obstruction
2. Remove small dorsal hump
3. Remove/reposition septal deformity
4. Correct tip deformity (note thick skin)
5. Correct low radix
6. Narrow bony base

Surgical Plan

1. Open approach with transcolumellar stairstep incision connected to bilateral infracartilaginous incisions
2. Component reduction of dorsum (2 mm) with concomitant radix augmentation
3. Septal cartilage harvest leaving a 10 mm L-strut
4. Correct intrinsic deformity of caudal L-strut with septal scoring, swinging door septal flap and anchoring to anterior nasal spine
5. Lower lateral crural turnover flaps to correct pinched tip appearance
6. Medial crural and interdomal sutures
7. Submucous resection and outfracturing of inferior turbinates
8. Lateral osteotomies (external perforated)

Comparison views of the patient's preoperative and 14-year postoperative appearance demonstrates correction of the deviation with redefinition of symmetrical dorsal aesthetic lines, correction of the dorsal hump, narrowing of the bony base, and refinement of the tip (without feminization). His subjective complaints of nasal airway obstruction resolved.

Patient Example 4

This healthy 41-year-old woman with Fitzpatrick type III thick nasal skin presented for cosmetic rhinoplasty without nasal airway obstruction. She was unhappy with the appearance of her dorsal hump and unrefined tip. This patient demonstrates the classic Middle Eastern nasal morphology. The frontal view demonstrates nasal deviation and a plunging tip with infralobular deficiency. Her lateral view demonstrates a large dorsal hump, a severely underprojected, underrotated, amorphous and plunging tip, as well as absence of a supratip break. She has an alar-columellar discrepancy with a retracted columella. Her basal view demonstrates nostril-tip imbalance with “short nostrils.” Intranasal examination was normal. Her dynamic examination revealed a hyperdynamic tip. Following primary rhinoplasty, she requested a more dramatic change in her tip, and this required a secondary soft tissue debulking operation.

Operative Goals

1. Remove large dorsal hump
2. Correct nasal deviation
3. Refine the tip and reestablish tip-defining points (note thick skin)
4. Drastically improve tip rotation and projection

Surgical Plan

1. Open approach with transcolumellar stairstep incision connected to bilateral infracartilaginous incisions
2. Component reduction of dorsum (5 mm)
3. Anterior septal angle reduction
4. Septal harvest (for cartilage grafting purposes) with 10 mm L-strut
5. Bilateral spreader grafts
6. Cephalic trim leaving a 6 mm rim strip
7. Columellar strut graft with medial crural septal sutures
8. Medial crural, interdomal and transdomal suturing
9. Combined infralobular and onlay tip graft
10. Lateral osteotomies (external perforated)

Comparison views of preoperative and 2-year postoperative appearance demonstrates a more balanced nose after reduction of the dorsum and refinement of the tip including improving tip rotation, projection and definition. The drastic improvement in overall nasal tip definition including enhancement of the supratip and infratip required a secondary operation with more soft-tissue debulking and visible onlay tip graft replacement secondary to early graft resorption. The necessity for secondary tip refinement or soft-tissue debulking is not uncommon in the Middle Eastern population and should be discussed during the initial informed consent.

Patient Example 5

This healthy 40-year-old African American woman with Fitzpatrick type VI thick nasal skin presented for cosmetic rhinoplasty without nasal airway obstruction. Her concerns were a wide and flat-appearing dorsum with a small dorsal hump deformity; an ill-defined, flat but bulbous tip; and widened ala. She wanted a narrower, more defined nose. The frontal view demonstrates a wide bony base, poorly defined dorsal aesthetic lines, a prominent bulbous tip with bifidity, and a wide alar base. Her lateral view demonstrates a small dorsal hump, decreased projection, and a class IV hanging alar deformity. Her basal view corroborates the bulbous tip deformity with bifidity and an increased alar base width. Intranasal examination was normal, as was her dynamic examination.

Operative Goals

1. Dorsal augmentation and definition
2. Narrow middle vault
3. Drastically refine tip and narrow tip-defining points (note thick-skinned patient)
4. Increase projection
5. Decrease alar base width

Surgical Plan

1. Open approach with transcolumellar stairstep incision connected to bilateral infracartilaginous incisions
2. Septal harvest (for cartilage-grafting purposes) with 10 mm L-strut
3. Cephalic trim leaving a 6 mm rim strip
4. Two-layer dorsal onlay graft (septal cartilage) for augmentation
5. Medial crural, interdomal and transdomal suturing
6. Columellar strut
7. Three-layer onlay tip graft (cephalic trim cartilage) for definition and projection
8. Medial osteotomies (internal)
9. Lateral osteotomies (external perforated)
10. Alar base resection

Comparison views of preoperative and 24-month postoperative appearance demonstrates nasal dorsum augmentation with concomitant narrowing of the middle vault and redefinition of the dorsal aesthetic lines. She has dramatic tip refinement with creation of well-defined tip-defining points, as well as an increase in projection. Her alar-columellar deformity has been corrected, as has her widened alar base deformity. She did not subjectively complain of nasal airway obstruction postoperatively.

Concluding Thoughts

Success in primary rhinoplasty is predicated on accurate preoperative analysis and clinical diagnosis, identification of both the patient's expectations and the surgeon's goals, and a thorough review of the plan of care and expected postoperative recovery. Intraoperatively, adequate anatomic exposure of the nasal deformity, preservation and restoration of the normal anatomy, correction of the deformity using incremental control, maintenance and restoration of the nasal airway, and recognition of the dynamic interplay between the composite of maneuvers optimize outcomes and lead to a successful experience for both patient and rhinoplasty surgeon.

Clinical Caveats

The key to a successful outcome begins with proper patient selection.

A thorough understanding of normal and abnormal nasal anatomy is paramount.

Accurate, precise, and complete nasofacial analysis is mandatory to help plan the operation.

Full and complete disclosure of all risks and benefits, including financial responsibilities, must be performed to both the surgeon's and patient's satisfaction. There is no substitute for an informed patient.

The surgeon should never enter the operating room without a well-thought-out plan.

The type of incision used is far less important than the correction of the underlying problem. Choose appropriately according to the deformity and your own experience.

If performing an open approach through a transcolumellar incision, one must avoid excessively debulking the tip and avoid alar base incisions that are greater than 3 mm outside the alar groove to preserve blood supply to the tip.

The procedure should proceed in an organized, stepwise fashion from skin to skin, without rushing. Iatrogenic injuries are difficult to correct.

The dorsal reduction should always be performed before harvesting septal cartilage, so that the 10 mm L-strut is maintained.

Continued

Clinical Caveats—cont'd

The dorsum must be reduced in component fashion to prevent an inverted-V deformity.

The surgeon should attempt to preserve the transverse processes of the ULCs.

Tip modifications should be performing using a graduated approach.

Webster's triangle should be preserved when osteotomies are performed.

All incisions must be closed meticulously.

The postoperative splints/tapes should be positioned carefully to prevent iatrogenic deformity.

The postoperative course should be reviewed with the patient and family before and after the operation.

Annotated Bibliography

Byrd HS, Hobar PC. Rhinoplasty: a practical guide for surgical planning. *Plast Reconstr Surg* 91:642-654; discussion 655-656, 1993.

An excellent article that describes nasofacial analysis using objective reference points.

Gunter JP, Rohrich RJ, Adams WP Jr. Dallas Rhinoplasty: Nasal Surgery by the Masters, 2nd ed. St Louis: Quality Medical Publishing, 2007.

A comprehensive two-volume text on all aspects of rhinoplasty. Multiple renowned contributors make this text an essential reference for the rhinoplasty surgeon, regardless of experience level.

Rohrich RJ, Gunter JP, Friedman RM. Nasal tip blood supply: an anatomic study validating the safety of the transcolumnellar incision in rhinoplasty. *Plast Reconstr Surg* 95:795-801, 1995.

An anatomic cadaver study evaluating the blood supply to the nasal tip via transcolumnellar, lateral nasal, and dorsal nasal branches. The results validate the ability to use the open approach (transcolumnellar incision) and maintain blood supply to the nasal tip. Suggestions are offered on how to avoid pitfalls that may result in embarrassment of nasal tip blood supply.

Sheen JH, Sheen AP. Aesthetic Rhinoplasty, 2nd ed. St Louis: Quality Medical Publishing, 1998.

Another classic comprehensive text. Authored by Jack Sheen, one of the preeminent master rhinoplasty surgeons.

CHAPTER 56

Tip Grafting for Nasal Contouring

WILLIAM D. LOSQUADRO, DEAN M. TORIUMI

Nasal tip contouring is perhaps the most difficult rhinoplasty skill to master. Seemingly isolated maneuvers can simultaneously affect multiple parameters on both the frontal and lateral views. The degree of difficulty is compounded by the relentless contraction of the skin–soft tissue envelope and the resultant potential for late complications. Early techniques in tip rhinoplasty were primarily reductive. The lower lateral cartilages were trimmed, scored, or divided to create smaller, albeit weakened, noses. Current techniques in tip rhinoplasty emphasize conservative lower lateral cartilage excision, suture reshaping, cartilage repositioning, and cartilage grafting.

One of the earliest reports of nasal tip cartilage grafting was by Peer in 1945. Through his histologic studies of grafts, he refuted the prevailing belief that septal cartilage was resorbed after transplantation, and he specifically described lengthening a retracted columella with septal cartilage. Hage in 1964 detailed the correction of dynamic alar collapse using auricular cartilage through, presciently, an open transcolumellar approach. Modern tip grafting techniques were first described by Sheen after he keenly observed that polly-beak deformities resulted from an overreduced nasal structure that was unable to accommodate a large skin–soft tissue envelope; his solution was to augment the tip with cartilage grafts placed through an endonasal approach. These techniques were later popularized through the external approach by Johnson and Toriumi.

Tip grafting is often performed in conjunction with conservative reduction of the lower lateral cartilages and suture contouring. Grafting significantly increases surgical complexity and the potential for postoperative complications and thus should not be used indiscriminately. A graded surgical algorithm may effect modest tip changes, such as narrowing and slight increases in projection, with conservative cartilage trimming and suture reshaping alone. Tip grafting can be used for greater changes, and grafting alone can lengthen or enhance the projection of a short nose, straighten a severely crooked tip, and reposition retracted alae. When used properly, cartilage grafting is a powerful tool for nasal tip contouring.

Indications and Contraindications

Indications for tip grafting in primary rhinoplasty include the increase of tip projection, prevention of postoperative loss of tip projection, nasal lengthening, straightening of tip deviations, and correction of cephalically positioned lower lateral cartilages. Mild increases in tip projection may be successfully achieved with suture

contouring (such as dome-binding sutures, lateral crural steal, and so on); increases greater than 1 or 2 mm frequently require tip grafts. The degree of augmentation and refinement, the anatomy of the existing nasal framework, and the skin thickness will further dictate the type of tip grafting employed.

Patients with weak lower lateral cartilages, short medial crura, and a deficient caudal septum are at risk for postoperative loss of tip projection. Extended columellar struts, caudal septal extension grafts, and caudal septal replacement grafts can each be used to stabilize the tip. These same grafts can also be used to lengthen short noses and correct persistent caudal septal deviations. Costal cartilage may be needed when lengthening a short nose to withstand the force applied by the stretched, contracting skin–soft tissue envelope.

Cephalically positioned lower lateral cartilages are another indication for grafting techniques. Aesthetically, cephalically positioned cartilages contribute to tip bulbosity, the parentheses tip deformity, and alar retraction. Functionally, they facilitate lateral wall collapse and decreased nasal valve patency. After dissection from both the nasal skin and vestibular mucosa, only very strong, flat lateral crura permit suture repositioning alone. Most cartilages lack adequate strength to support the lateral wall and will require placement of lateral crural strut grafts to prevent postoperative alar collapse and retraction.

No absolute contraindications to tip grafting exist, although grafting is sometimes unnecessary. Primary rhinoplasty patients with adequate projection, proper rotation, and minimal tip bulbosity may successfully be treated with conservative trimming of the cephalic lateral crura and suture contouring. Overly long noses may be better addressed by setting the medial crura back on the caudal septum in a tongue-in-groove fashion. Desired aesthetic changes must be balanced against the increased risk of complications posed by grafting.

Pertinent Anatomy

The nasal tip proper is one of the nine aesthetic subunits of the nose. Within the context of nasal tip contouring, the term *tip* more accurately reflects the lower third of the nose, specifically the tip, ala, soft tissue triangle, and columellar subunits. The transition points between these subunits contribute substantially to tip highlights and shadows.

The external appearance of the nasal tip is dictated primarily by the anatomy of the lower lateral cartilages and the caudal septum. Projection and rotation are the primary metrics analyzed when viewing the tip profile. Other important parameters are the alar-columellar relationship, the columellar-lobular angle or double break, and the supratip break. Ideal tip projection has been quantified by assorted mathematical equations and anatomic relationships. Yet adequate projection is often best determined by simple observation of each patient's anatomy—particularly dorsal height, nasal length, and chin projection. Ideal rotation in males is approximately 90 to 100 degrees and 100 to 120 degrees in females. The perceived rotation is affected by the position and contour of the nasolabial angle. A gentle curve is desirable; a sharp transition makes the angle appear more acute and unnatural.

The alar-columellar relationship can significantly affect the perceived harmony of the tip profile. Alar retraction creates a snarled appearance that mars an appropriately projected and rotated tip. Approximately 2 to 4 mm of columellar show is generally considered aesthetic. Greater show may result from alar retraction or a hanging columella; less show may be caused by hanging alae or retracted columella. The alar rim contour should approximate a gentle curve. Whereas alar retraction is characterized by a more uniform arc of elevation, alar notching describes an acute, focal retraction that interrupts the ideal contour.

The double break and supratip break are other important components of an aesthetic tip. The double break is formed by the natural divergence of the intermediate crura. The cephalic break point corresponds to the tip-defining points on the frontal view and represents the transition from the domes to the lateral crura. The caudal break point represents the initial divergence of the medial crura into the domes and can be difficult to appreciate on frontal view. The area between these two points forms the infratip lobule. The transition from the tip-defining point to the dorsum forms the supratip break. The dome height over the anterior septal angle and the skin thickness draping over it creates the break. A 1 or 2 mm supratip break is especially desirable in females, whereas males may tolerate less or no supratip break.

The tip profile is primarily a two-dimensional relief against a uniform background; subtle shadows and highlights compose the frontal view. When using a single midline light source, the tip highlight predominates. Ideally, it is a horizontally oriented ellipse formed by the divergence of the intermediate crura and the paired domes. The paired tip-defining points are more prominent when two light sources are used. The average width between tip-defining points is reportedly 8 mm, although this distance should be individualized based on overall facial width, base width, and cultural norms.

Cephalic to the tip highlight there should be a subtle shadow that represents the supratip break. Greater supratip breaks cast darker shadows. The tip highlight should gradually transition to the alae without a deep shadow. A concave transition between the tip and alae isolates the tip with shadows and creates the so-called parentheses deformity; this may be caused by bulbous or cephalically positioned lower lateral cartilages. An unnatural, single midline tip highlight may be seen in patients whose domes have been pinched together. On the basal view, a pinched tip will exhibit marked alar concavity.

Overall tip shape and size are crucial to tip aesthetics. A bulbous tip interrupts a smooth brow-tip aesthetic line. Bulbosity may result from both enlarged and cephalically positioned lateral crura. The ideal lateral crura position can range from 35 to 45 degrees off the midline; more simply, they should point towards the lateral canthus as opposed to the medial canthus.

Even after performing a cephalic trim, cephalically positioned lateral crura can leave residual tip fullness that tends to obliterate the subtle sidewall inflection at the confluence of the sidewall, tip, and ala.

The relationship of the infratip lobule to the ala is another important component of the frontal view, and the ideal contour is a gently curving V, or “gull in flight.” Prominence of the infratip lobule, tip rotation, and alar position all contribute to this contour. It is exaggerated by a prominent, “hanging” infratip lobule and reduced by a hidden, flattened infratip lobule. An underrotated tip also creates an unsightly shadow at the nasolabial angle.

Preoperative Assessment

The surgeon begins the preoperative assessment by eliciting the patient's functional and aesthetic concerns. Understanding the patient's surgical goals is crucial to a successful surgeon-patient relationship. Some patients request correction of obvious deformities, such as a dorsal hump or bulbous tip, whereas others provide annotated photographs detailing a multitude of changes. Some want to address a single deformity, such as male patient who wants a less bulbous tip but is unconcerned with a slight dorsal convexity. Ethnic patients may ask for subtle changes that maintain their ethnicity, or they may desire a more refined nose.

Identifying patients with unachievable aims or goals beyond the surgeon's aesthetic range is paramount. Patients with goals that are unattainable rarely have body dysmorphic disorder; they more commonly request changes that are not anatomically feasible. For instance, a finite reduction is achievable in a patient with thick skin, a large dorsal hump, and overprojected nasal tip without developing a polly-beak deformity; however, a small, petite nose is unrealistic. Other patients may desire changes that are displeasing to the surgeon's aesthetic sensibilities, such as a scooped dorsum or arched alae. These goals may be surgically attainable, and the patient may indeed be happy postoperatively. However, a dissatisfied patient is both unhappy and aesthetically worse. All of these patients are poor candidates, and the surgeon should politely decline to operate on them.

The patient's past surgical history should be obtained. The timing and number of prior septoplasties, rhinoplasties, and cartilage-harvesting procedures are recorded. Proper preoperative counseling requires that the surgeon be aware of available grafting material and whether alloplastic implants or injectable fillers have been used previously. Operative reports may detail implants unknown to the patient, although the accuracy may be unreliable. Many surgical decisions will thus require direct intraoperative inspection.

The patient's past medical history should also be elicited, particularly rhinologic complaints such as nasal obstruction, congestion, epistaxis, and rhinorrhea. Patients with allergic rhinitis should be counseled that medical intervention will be necessary to alleviate their symptoms rather than surgery. A history of bleeding diatheses, asthma, chronic obstructive pulmonary disease, diabetes, and immune disorders is also important, because these will have an impact on intraoperative management and postoperative healing. The patient's medication usage should be recorded, particularly nasal decongestant sprays.

For most primary and secondary rhinoplasties, smoking is not a contraindication, although the increased risk of infection, tissue necrosis, and prolonged healing should be discussed. Complex revisions of skin-soft tissue envelopes damaged by infection,

fillers, or alloplastic implants are at a much higher risk for complications and should be delayed until the patient stops smoking completely. Ideally, all patients should quit smoking 6 to 8 weeks before surgery.

The physical examination begins with visual inspection of the frontal, lateral, and basal views. The external manifestations of various anatomic irregularities were discussed in the previous section. Palpation helps to assess the strength of the lower lateral cartilages and caudal septum. In revision patients, palpation will aid in differentiating soft tissue from structural abnormalities and assessing the elasticity of damaged skin.

Anterior rhinoscopy with a nasal speculum can identify caudal septal deviations, internal nasal valve collapse, and inferior turbinate hypertrophy. It is prudent to perform nasal endoscopy in any patient who complains of nasal obstruction. A rigid zero-degree scope can be introduced under direct visualization or with a camera and monitor. The presence of a septal perforation, synechiae, polyps, concha bullosa, or mucopurulent drainage necessitates additional rhinologic workup.

Photography is an integral component of the rhinoplasty consultation. Standard views include frontal, lateral, oblique, and basal views. Photographs are taken with two umbrella lights each positioned behind the camera at a 45-degree angle to the patient. A frontal photograph with a single midline umbrella light positioned behind the camera improves the contrast between light and shadow and provides better visualization of nasal contours. Additional views include closeups of all standard views, an inspiratory basal view to assess external valve collapse, and smile views. Patients with vertically oriented smiles (that is, the corner of the mouth goes up instead of moving laterally) who will be undergoing placement of an extended spreader graft may develop a transverse upper lip crease when they smile.

Imaging software is an excellent tool for demonstrating operative goals. Modified photographs can help patients communicate their goals more effectively and provide the surgeon with a visual surgical template. It is imperative, however, that realistic imaging of an obtainable outcome be shown. In the senior author's practice (D.M.T.), preoperative digital imaging is performed, and copies of these simulated results are provided for the patient to take home. He or she is encouraged to review the photographs and schedule another visit if modifications or clarification is necessary. However, producing virtual results with the patient present should only be performed after considerable experience, because it requires deft use of the software and knowledge of what is surgically achievable. Likewise, photo imaging should not be performed by ancillary staff, who may not have knowledge of realistically achievable results. If used properly, photographic imaging can be a powerful tool in the surgical practice.

Preoperative Planning

Patients are positioned supine on the operating room table with the head supported by foam. Operative frontal, lateral, and basal photographs are taken after intubation.

Convexities and concavities are marked before local anesthetic is injected so that deformities can continue to be identified despite the inevitable edema from the injection and operative manipulation. Local injection of the tip, nasal spine, dorsum, side-walls, septum, and vestibular mucosa incision lines is then performed with 1% lidocaine with 1:100,000 epinephrine. Vigorous injection of the septum facilitates hydrodissection of the mucoperichondrial flaps.

An inverted-V incision is outlined midway between the superior extent of the columella and the medial crural footplates. A straight-line columellar incision should be avoided to prevent scar contracture and columellar notching. In patients whose noses will be deprojected, the incision should be outlined slightly higher to accommodate its eventual inferior movement.

Operative Technique

Incision and Dissection

The various benefits and drawbacks of endonasal and open rhinoplasty are a frequent topic of debate. Many advanced tip-grafting techniques require suture fixation and are best accomplished by the open approach. Flap elevation and closure warrants close attention and meticulous technique.

The anterior columellar portion of the incision is performed with a No. 11 blade. For precise incision placement, the blade is moved in a sawing motion. The lateral limbs are incised very superficially to avoid transecting the medial crura. The vestibular portion of the columellar incision is more easily completed with a No. 15 blade. Grasping and turning the tip with the left hand exposes the columella. The incision is extended up toward the vestibular apex, but not blindly into it.

The marginal incisions are performed next. Using a wide double-pronged skin hook, the lateral crura are exposed. Gentle palpation with the scalpel can help identify the caudal edge of the lateral crura. The incision is then performed from lateral to medial but is stopped short of the vestibular mucosa beneath the dome. At this point the marginal incision has not yet been connected to the columellar incision.

Elevation of the skin–soft tissue envelope over the medial crura begins using Converse scissors, exercising care to avoid transecting the medial crura. As the dissection approaches the intermediate crura, it is important to dissect within the suprapreri-chondrial plane. This plane is often identified by its wispy connective tissue and lack of bleeding.

Once the skin flap has been elevated over the intermediate crura, the marginal incisions can be completed. A wide double prong skin hook is used to expose the vestibular apex and the incision is completed with the Converse scissors. Direct visualization permits precise incision placement. Dissection over the domes is facilitated by simultaneous caudal lower lateral cartilage retraction and cephalad skin flap retraction. Careful dissection over the lateral crura ensures that the caudal margin is not inadvertently transected.

Dissection continues in the suprapreri-chondrial plane onto the anterior septal angle and over the upper lateral cartilages; a Converse retractor facilitates visualization beneath the flap. Once the rhinion is encountered, the nasal bone periosteum is incised with the sharp edge of a Joseph periosteal elevator. The periosteum is raised off the nasal bones with the Joseph elevator.

Septal Cartilage Harvest

Septal cartilage is the first choice for grafting material because of its location, strength, and flexibility. There are multiple approaches for septal cartilage harvest; the choice depends on the work to be undertaken. A Killian incision may be used for rhinoplasties in which repositioning of the tip, columella, or nasal base is not necessary. If more extensive work is needed and the nose requires shortening, lengthening, rotation, or deprojection, dissection between the medial crura to expose the caudal septum may be beneficial. The interdomal space is divided, and dissection is carried onto the anterior and posterior septal angles; extended dissection requires division of the upper lateral cartilages from the dorsal septum. Entering the interdomal space and separating the upper lateral cartilages allow maximal septal exposure and precise control of nasal base and tip position.

Mucoperichondrial flap dissection in the subperichondrial plane ensures a relatively bloodless dissection. The proper plane is entered by scoring the septum with a No. 15 blade and then dissecting the flap with a Freer elevator. Dissection is carried back to the bony-cartilaginous junction bilaterally. If the bony septum is deviated, flap elevation continues posteriorly and the deviated portion is resected.

In harvesting septal cartilage, it is important to leave a 1 to 1.5 cm L-strut intact to provide nasal support. Additional cartilage may be left beneath the keystone area of the upper lateral cartilages to ensure dorsal support, particularly in patients with short nasal bones. Careful dissection of posterior septal cartilage between the perpendicular plate of the ethmoid bone and the vomer will ensure maximal length to the septal graft.

Costal Cartilage Harvest

Details of costal cartilage harvesting and carving are presented in Chapter 59. It is worth reiterating, however, that postoperative warping can be avoided by early and sequential intraoperative graft carving. Somewhat counterintuitively, bent pieces are often preferred to straight pieces, because the warping has commenced in the operating room and can be used to the surgeon's advantage.

Nasal Base Stabilization

The nasal base is the foundation of the lower third of the nose and maintains tip position; anatomically, it is composed of the caudal septum and its soft tissue attachments to the lower lateral cartilages. Stabilization of the nasal base is a prerequisite for tip contouring. A weak nasal base requires overcorrection of projection and rotation in anticipation of postoperative loss of projection. Consistent results require precise intraoperative tip positioning on a stable base that is resistant to postoperative skin–soft tissue envelope contraction.

A graduated approach to nasal base stabilization is prudent. Patients at risk for postoperative loss of tip projection are those with weak lower lateral cartilages, a short caudal septum, and short medial crura. The nasal base of patients with long, strong medial crura can be stabilized with a columellar strut placed into a pocket dissected between the medial crura. In patients requiring rotation or shortening, the medial crura can be fixed to the midline caudal septum in a tongue-in-groove fashion.

Patients requiring nasal lengthening or significant projection need strong support to resist the skin–soft tissue envelope contractile forces. Lengthening is accomplished with a caudal septal extension or replacement graft. Caudal septal extension grafts can be placed end-to-end or overlapped, depending on the position of the caudal septum. End-to-end grafts are stabilized with two sets of bilateral splinting grafts sutured with 5-0 PDS sutures. A slightly deviated caudal septum can be lengthened

with an overlapping graft if the caudal margin of the graft is midline. The graft is secured with horizontal mattress 5-0 PDS sutures. The overlapping cephalic edge of the graft is beveled so the airway is not obstructed. End-to-end grafts are preferred because they are less likely to cause deviation or airway obstruction.

Patients with a severe caudal septal deviation, deficient septum, or nasal cant may benefit from a caudal septal replacement graft. In these cases, the caudal septum is removed while a strong dorsal strut is left intact. Spreader grafts are inserted up to the osteocartilaginous junction and extend beyond the end of the dorsal strut to stabilize the caudal septal replacement graft. Dissection is carried down through the interdomal space onto the nasal spine. After removal of the caudal septum, a straight 5 mm osteotome is used to make a notch in the nasal spine and set the midline of the nasal base. Creation of a wedge-shaped notch acts as a graft fixation point and allows precise and stable graft placement. The nasal spine may not be centered, such as in deviated noses, and the notch may need to be set off of the nasal spine midline. Before graft placement, two 4-0 PDS sutures are placed through the periosteum on each side of the notch and left untied. If no tissue is available for suture placement, a hole can be drilled through the nasal spine with a 16-gauge needle. Once the graft is placed within the notch, the suture is passed back through the graft and tied.

Cartilage from the septum or rib is preferred for caudal septal replacement and extension grafts. Equivalent strength with auricular cartilage requires thicker grafts, which can excessively widen the columella and block the airway. Costal cartilage is strong enough to resist postoperative contractile forces in complex revisions where scarred skin–soft tissue envelopes need lengthening and projection.

Tip Projection

Multiple techniques are available to increase tip projection. Minor increases in projection can be obtained with suture contouring alone. Dome-binding sutures can be placed within the native domes or used to recruit lateral crura. The lower lateral cartilages may also be advanced on a stable nasal base and fixed with transeptal 4-0 plain gut sutures. This technique will blunt the nasolabial angle, which may or may not be a beneficial change. When these techniques prove insufficient, tip grafting is required.

Mild increases (1 or 2 mm) in tip projection can be attained with tip onlay grafts. These grafts are trimmed into a rectangular or elliptical shape to simulate the ideal tip highlight and are sutured directly over the domes in a horizontal orientation. Any type of cartilage may be used, although the cephalic trim of the lateral crura is ideal for mild increases, because its soft edge blends easily with the native cartilages. For greater increases in projection, thicker or multiple pieces of septal cartilage or soft tissue may be necessary.

Larger increases in projection can be obtained with shield tip grafts. The graft shape simulates the divergent intermediate crura and paired tip-defining points. Beveled edges facilitate graft camouflage. The shield tip graft is sutured to the intermediate crura and projects above the domes. The additional projection carries an increased risk of graft visibility, particularly in patients with thin skin. However, the graft's leading edge stretches and thus refines the thick-skinned tip. Slight graft flexion, often caused by compression from the skin–soft tissue envelope, helps preserve the double break. Support grafts (cap or buttress grafts) can be placed behind the shield graft to resist excessive cephalic pressure.

Smoothing the transition from the shield graft to the lateral crura is crucial to preserving a smooth tip–alar lobule junction and preventing shadows that isolate the tip. Lateral crural grafts extend from the existing lower lateral cartilages to the posterosuperior aspect of the shield graft and are secured with 6-0 PDS suture. They are used primarily when the shield graft projects more than 3 mm above the existing dome structures.

Skin thickness dictates the amount of camouflage necessary to prevent graft visibility.

Thick skin may require none, whereas thin skin requires several layers. Perichondrium is an excellent tissue for this purpose, especially thick, fibrous, costal perichondrium. Gently crushed septal cartilage, auricular cartilage, or scar tissue is also useful. These materials can be sutured over or around the leading edge of the shield graft to prevent graft visibility.

Greater tip projection increases the distance between the domes and anterior septal angle, thus increasing the supratip break. The visible supratip break reflects the skin thickness draped over this height. In a projected tip on a stable base, 4 to 6 mm between the dome and anterior septal angle is appropriate for thin skin, whereas 8 to 12 mm may be needed for thick skin. Too large a supratip break may appear as a scooped dorsum or mild saddle deformity. Supratip grafts can be sutured to the cartilaginous dorsum to ease the transition and improve the overall nasal profile.

Tip Rotation

Smaller degrees of tip rotation can be achieved simply by placing a columellar strut and dome-binding sutures. This maneuver will increase tip projection and often produce moderate tip rotation; the amount of rotation depends on the prominence of the caudal septum and its contribution to the ptotic tip. Trimming the caudal septum can result in tip rotation but is unreliable. Tip rotation can also be achieved by shortening the lateral crura or by performing a lateral crural division and overlay (the lateral crural steal technique described by Kridel and colleagues). Alternatively, tip rotation can be controlled by setting the medial crura into position about the native or extended caudal septum.

When excessive nasal length is caused by a redundant caudal septum, tip rotation can be achieved by dissecting between the medial crura and suturing them to the existing caudal septum. This maneuver will result in shortening of the nose and rotation of the nasal tip. The caudal septum is not trimmed but rather used as a fixation point to create tip rotation. The degree of rotation can be increased by moving the domes more cephalad than the lower segment of the medial crura. Once rotation is achieved using this method, there may be redundancy of the lateral crura that may require dissection of the lateral crura and repositioning. Maneuvers used to rotate and project the tip may also flatten the infratip lobule. Lack of a double break on tip profile will give the nose an unnatural, beaklike appearance. Infratip grafts can be sutured to the medial crura to recreate the ideal contour.

Tip Refinement

Tip refinement refers to the overall size, shape, and definition of the tip. The shape and width of the domes and the size and position of the lateral crura determine whether the tip is aesthetically pleasing. Large lateral crura should be trimmed cephalically; leaving behind 8 to 10 mm of width is advisable, although the precise amount resected depends on the shape and intrinsic strength of the cartilages. Dome-binding sutures refine and narrow the tip. Residual tip bulbosity after trimming and suture contouring is often caused by cephalically oriented lateral crura or residual deformity of the lateral crura. Dome-binding sutures may also deform the lateral crura by leaving an unnatural bulge lateral to the dome sutures or near the alar groove.

Lateral crural strut grafts can be used effectively to reposition the lower lateral cartilages, refine the tip, and enlarge the nasal airway. Lateral crural strut grafts are sutured to the undersurface of the lateral crura to position the cartilages in a flatter, stiffer orientation; they can then be effectively narrowed without bulging laterally. The lateral crura are freed from the underlying vestibular mucosa; local anesthetic is injected to facilitate the dissection. Septal cartilage is strong and flexible but not always available. The strength of costal cartilage permits reduced graft thickness at the expense of increased tip rigidity. Auricular cartilage is often too thick for this application. Grafts are generally 1 to 1.5 mm thick, 5 mm wide, and 25 to 30 mm long, although the exact length depends on the degree of airway collapse and alar retraction.

The position of the domes can be altered with lateral crural strut grafts. This technique is applied primarily in an overprojected nose to decrease tip projection and counterrotate the tip. Precise positioning of the medial graft edge creates a new tip-defining point along the intermediate crura or medial to the original dome. Positioning the lateral crural strut graft medially moves the old dome lateral to the new one and deprojects and counterrotates the tip. The new dome's position is fixed by placing transdomal 5-0 PDS sutures through the medial margin of the graft and native lower lateral cartilages; the suture is tied between the new domes to hide the suture knot. A limited increase in tip projection can be obtained by moving the medial margin of the lateral crural strut graft lateral to the existing dome. Tip projection is more commonly increased by advancing the nasal base on a stable strut or extension graft or with a shield tip graft.

Cephalically oriented lateral crura can be repositioned once lateral crural strut grafts are in place. A pocket is dissected caudally in the alar skin–soft tissue envelope with Converse scissors. The pocket is typically placed just caudal to the alar groove. Placement of the strut graft within this pocket will decrease the cephalic tip bulbosity and

improve retracted alae. Precise placement of the pockets is critical to producing symmetrical alar margins and nostrils. If the nostril shapes or alar margins are asymmetrical preoperatively, the two pocket locations must be altered to compensate for these differences.

In complex revision cases, the native domes and lateral crura may be severely deformed by scar tissue, multiple grafts, and overresection. If no useable intermediate or lateral crura exist, new ones can be shaped from dome replacement grafts.

Dome replacement grafts are first sutured to the existing medial crura; in some cases, they can be sutured directly to the caudal septal extension or caudal septal replacement graft. Soft, flexible tissue is ideal for the dome grafts. Thin septal cartilage, scar tissue, and rib perichondrium are good options, although a remnant lateral crural graft with attached scar tissue is ideal because of its flexibility and strength. Lateral crural strut grafts can be sutured to the lateral aspect of the dome replacement grafts to provide lateral wall support. They should measure 25 to 32 mm in length depending on the size of the nose and the amount of lateral wall support needed. Ideal lateral crural strut grafts are slightly curved, and the concave side is oriented toward the nasal airway to ensure airway patency. Once the lateral crural strut grafts are in place, domes can be created by placing 5-0 PDS dome sutures bilaterally.

Nostril Reshaping

In addition to base reduction techniques, nostrils can be reshaped with grafting. Lateral crural repositioning is perhaps the most powerful method of pulling down retracted alae and recreating nostril shape on frontal view. Lateral crural overresection in traditional reductive rhinoplasties often led to alar collapse that isolated the tip in circumferential shadows. Alar retraction exaggerates the “gull in flight” contour on frontal view and contributes to the abnormal alar-columellar relationship on profile. As previously described, lateral crural strut grafts can be used to reposition the alae more caudally. It is essential to make the pockets for the repositioning caudally and down to the piriform aperture to ensure adequate alar movement. When moving the ala caudally, the pocket created for the lateral crura should be even more caudal and closer to the alar margin. Often this maneuver will result in increased alar flare, which must be addressed with alar base reductions.

Further improvement in nostril shape can be obtained with alar rim grafts. These can help recreate and support the tip-alar transition and correct alar concavities. Alar rim grafts are typically 2 to 3 mm wide and 12 to 15 mm long. A pocket is carefully dissected caudal to the marginal incision, and the graft is slid into the pocket. It is held in place with a single 6-0 Monocryl suture. The medial graft edge should be gently crushed with Adson-Brown forceps to prevent visibility. Alar rim grafts help correct the alar concavities seen on the basal view and create a smooth transition from tip lobule to alar lobule.

Closure

Closure begins by reapproximating the skin flap with a single deep 6-0 Monocryl suture. The marginal incisions are then carefully approximated with 5-0 chromic gut; poor reapproximation can lead to the development of vestibular webs and nasal valve stenosis. The columellar skin is closed with 7-0 nylon vertical mattress sutures placed perpendicular to the incision line apices. Precise closure at the columellar edge is crucial to prevent visible contour irregularities. The spaces in between are then filled with vertical mattress or simple interrupted sutures, depending on the amount of eversion needed. The vestibular portion of the columellar incision is closed with single interrupted 6-0 fast-absorbing gut sutures. Meticulous technique helps to camouflage the scar.

Lateral wall splints fashioned from 0.25 mm bivalve septal splints facilitate integration of lateral crural struts. The bivalve septal splint is cut in half and the edges trimmed. One piece is placed intranasally and the other across the sidewall and ala. The splints are sutured in place with a single 3-0 nylon suture placed through-and-

through the sidewall, and the knot is tied intranasally. To account for the lateral wall edema and prevent skin ulceration or necrosis, the knot should be loose enough to allow passage of a needle-holder tip. Folded, nonadherent gauze packs are placed bilaterally, depending on the quantity of intraoperative bleeding. Vestibular splints also fashioned from 0.25 mm bivalve septal splints may be placed to stent constricted airways and to help preserve the lateral position of lateral wall grafts.

A narrow strip of nonadherent gauze is placed over the dorsum from the radix to the supratip. The nose is then taped with ¼-inch reinforced paper tape, and a thermoplastic cast is applied to the dorsum. Bacitracin is applied to all suture lines. A gauze drip pad is placed across the nose. Nonadherent gauze and a transparent dressing are used to cover the chest incision at the harvest site.

Postoperative Care

A broad-spectrum antibiotic is prescribed postoperatively for up to 2 weeks. Patients are encouraged to take acetaminophen for pain, although hydrocodone/acetaminophen pills are prescribed for more severe pain. Nonadherent gauze packing and vestibular splints are removed on postoperative day 1. The chest dressing is removed on postoperative day 2. The columellar and chest sutures, nasal cast, and lateral wall splints are removed on postoperative day 7. Alar base reduction sutures are removed on postoperative day 14. Patients return to the office for two additional visits the first month, monthly for the next two visits, and then bimonthly for two visits.

Correction of minor asymmetries with compression maneuvers can begin 3 weeks after surgery. Patients are directed to apply pressure to specific areas for 1 minute 10 times daily. Silicone sheeting is provided for chest wounds 3 weeks after surgery. Patients are instructed to tape the sheeting over the scar nightly and clean it with alcohol in the morning; sheets are changed monthly.

Walking may begin on postoperative day 1, but patients are asked to refrain from strenuous physical activity for 6 weeks. Swimming is restricted for 4 weeks; afterward patients may swim in chlorinated pools only for the next 2 months. Patients may wear glasses while their cast is still in place. Thereafter, patients are asked to bring glasses to the office so that their resting position on the nasal bridge can be assessed.

Problems and Complications

The most common complication after surgery is residual asymmetries, especially in difficult revisions or congenital or traumatic cases. The likelihood that asymmetries may develop is strongly correlated with the patient's skin thickness. Thick skin remains edematous for much longer after surgery and will tend to hide many irregularities; even minor irregularities will show through thin skin.

Nostril asymmetry can be one of the most difficult problems to correct in revision patients. Preference is given to aligning nostrils on frontal view. An appropriate alar-columellar relationship on lateral view is the next goal in nostril reshaping. Symmetry on the basal view is the most difficult to achieve, but fortunately the least visible.

Additional complications include bleeding, infection, and scarring. Epistaxis is uncommon after surgery and can often be treated with oxymetazoline spray. Recalcitrant bleeding may require application of hemostatic agents, packing, or operative intervention. The risk of infection is very low but increases substantially in patients who have had multiple procedures. Any suspicion of nasal cellulitis should be treated quickly and aggressively. A low threshold for incision and drainage in the operating room is prudent, since chronic abscesses can smolder and destroy nasal cartilage grafts or, in the worst cases, irreparably damage the skin envelope.

Careful attention to closure of the transcolumellar incision can maximize scar camouflage. Poor scars can be treated with dermabrasion or revision. Improper closure of marginal and intracartilaginous incisions can lead to vestibular scarring. Even the smallest scars or webs can compromise the internal nasal valve and drastically decrease nasal airflow. Repair often requires placement of an auricular composite graft.

Base reduction and chest incisions can be especially troublesome, particularly in thick-skinned ethnic patients, such as Asians and mestizos. Silicone sheeting, steroid injections, and dermabrasion can all be used to improve the appearance of hypertrophic scars.

Results

This 17-year-old patient requested nasal refinement. She reported nasal dyspnea during exercise. On frontal view, she had a narrow dorsum, lateral wall pinching, and a bulbous tip with a typical parentheses deformity. On lateral view, she had a dorsal hump, underprojected tip, and an obtuse nasolabial angle. Additionally, she had an underprojected chin. On basal view, she had flared medial crura, a wide columella, and a trapezoidal configuration secondary to her wide tip and lateral wall collapse. Intranasal examination revealed a septal spur along the floor of the left nasal cavity. She also exhibited external valve collapse on inspiration.

Surgical Plan

Correction of the patient's nasal airway obstruction required repositioning the cephalically positioned lateral crura. A small caudal septal extension graft was placed to support the nasal base. Spreader grafts were placed to correct the middle vault pinching. The lateral crura were dissected from the vestibular skin and supported with lateral crural strut grafts. The lateral crura were then positioned caudally to correct the cephalically oriented cartilages. A small, soft cartilage graft was placed over the domes to provide some additional tip projection and narrowing. Alar rim grafts were used to create a smooth transition from the tip lobule to the alar lobule. The rhinoplasty worksheet demonstrates the maneuvers performed during her surgery.

Bilateral lateral crural strut grafts, dome sutures, and lateral crura caudal repositioning
Bilateral alar rim grafts
Bilateral alar batten grafts

Crushed cartilage placed over domes

One year postoperatively, she has smooth brow-tip aesthetic lines, improved dorsal width, and a narrower tip. She no longer has a parentheses shape to her nasal tip, and the shadowing of her tip is more favorable. On lateral view, she has a smooth dorsum, increased projection, and an improved nasolabial angle. The basal view reveals a triangular configuration, lateral wall support, and increased nostril size.

This 19-year-old patient requested rhinoplasty. On frontal view, she had a wide tip and a hanging infratip lobule. On lateral view, she had a slight dorsal hump, an underprojected tip, and an underprojected chin. Her nose appeared dependent because of the downward cant to the nostrils. On basal view, she had flared medial crural footplates and a trapezoidal shape consistent with her wide tip lobule.

Surgical Plan

The primary goal was to increase the patient's nasal tip projection. Stabilization of the nasal base using a caudal septal extension graft was an important step in the surgery. The extension graft overlapped the septum slightly and was stabilized with splinting grafts. A dorsal hump reduction was performed and lateral crural strut grafts were placed. The lateral crura were then moved caudally to correct their cephalic position. Onlay tip grafts were placed horizontally over the domes to provide additional tip projection. Bilateral medial and lateral osteotomies were performed. Alar rim grafts contributed to proper tip contour. The rhinoplasty worksheet illustrates the steps performed during her surgery.

Lower lateral cartilage

Upper and lower lateral cartilages

Surgical Steps

Submental incision with submental liposuction and placement of a small Silastic extended chin implant

Inverted-V midcolumellar incision connected to bilateral marginal incisions
Dorsal hump rasping
Bilateral medial and lateral osteotomies to narrow the upper third
Open septoplasty and septal cartilage harvest
Bilateral spreader grafts

Caudal septal extension graft overlapping the left side of the septum and stabilized with right splinting graft
Bilateral cephalic trim of lateral crura

Bilateral lateral crural strut grafts, dome sutures, and lateral crura caudal repositioning
Crushed cartilage on domes
Bilateral alar batten grafts

Two years postoperatively, she has a more refined tip and an improved alar-columellar relationship. On lateral view, she has a straight dorsum, increased tip projection, and more favorable angulation of her nostrils. The refined tip and increased projection is reflected in the triangular shape of her nasal base.

This 46-year-old female patient requested rhinoplasty. On frontal view, she had a narrow dorsum, bulbous tip, and hanging infratip lobule. On lateral view, she had a prominent dorsal hump, overprojected tip, hanging columella, and short upper lip. The basal view revealed a wide, bifid tip and short medial crura.

Surgical Plan

This patient underwent an external rhinoplasty approach and reduction in the overall size of her nose. Fortunately, she had relatively thin skin that was able to contract over time. (If she had had thick skin, there would have been a limitation to the amount of skin shrinkage that could occur, and this would have limited the degree of deprojection and downsizing that her nose would have tolerated.) She had a very large, harvestable segment of septal cartilage. After conservatively trimming the caudal septum, the medial crura were set back and sutured to the septum in a more inferior position to decrease tip projection. This maneuver relaxed the upper lip and created a more favorable nasolabial angle. Dorsal hump reduction was performed and spreader grafts were placed. The lateral crura were dissected from the underlying vestibular skin. Lateral crural strut grafts were sutured to the undersurface of the lateral crura, medial to where the original domes were located, to move the new domes medially and further deproject the tip. Dome sutures were placed to narrow the tip. The lateral crura were then repositioned caudally to correct their cephalic positioning. Additional cartilage was needed, so auricular cartilage was harvested and used for alar batten grafts and alar rim grafts. Alar base reductions were performed to decrease the excess nostril size caused by deprojecting the tip. The rhinoplasty worksheet illustrates the maneuvers performed during her surgery.

 Open septoplasty and septal cartilage harvest
 Bilateral spreader grafts with two on the right side
 Tongue-in-groove setback of medial crura onto caudal septum with deprojection
 Bilateral cephalic trim of lateral crura

Bilateral lateral crural strut grafts, dome sutures, and lateral crura caudal repositioning; domes moved medially to decrease tip projection
 Right auricular cartilage harvest through postauricular incision
 Bilateral auricular cartilage alar batten grafts
 Bilateral alar rim grafts

Auricular perichondrium and crushed cartilage over domes.

Downsizing the patient's nose left redundant skin, which caused tremendous swelling and a very wide nose in the early postoperative period. It took many months for the redundant skin to shrink. After 18 months, she has smooth brow-tip aesthetic lines and a narrower, more refined tip. On lateral view, she has a straight dorsum, decreased projection, a shorter nose, and a softer nasolabial angle. Shortening her nose has resulted in a longer upper lip. The basal view reveals a rounder tip lobule without bifidity.

This 51-year-old woman complained of nasal deformities and obstruction. She had undergone a primary rhinoplasty 13 years before and a revision 1 year thereafter. On frontal view, her nose was deviated to the right. She also had collapse of the left upper lateral cartilage and pinching of the tip. On lateral view, her nose was under-projected with a mild polly-beak deformity. The basal view revealed left lateral wall collapse and nasal deviation to the right. Intranasal examination revealed a high left septal deviation obstructing the nasal valve and a right posterior septal deviation.

Surgical Plan

A secondary rhinoplasty was performed using the external rhinoplasty approach. Costal cartilage was harvested to obtain adequate cartilage for grafting. The patient had significant weakness in the nasal tip from previous overresection of the lower lateral cartilages. She had a severely deviated caudal septum that required replacement with a caudal septal replacement graft. This graft supported what remained of the lower lateral cartilages. Spreader grafts were placed to correct the middle nasal vault collapse. The weak, damaged lateral crura were stabilized with lateral crural strut grafts, and the lateral crura were repositioned caudally. Harvested septal cartilage was used for the lateral crural strut grafts to provide a softer nasal tip. Soft cartilage was placed over the domes to provide additional tip projection. A septal cartilage dorsal graft was placed to increase the dorsal height. The rhinoplasty worksheet illustrates the steps performed during her surgery.

Bilateral septal cartilage alar batten grafts

Bilateral alar rim grafts

Crushed cartilage and perichondrium over domes

Septal cartilage dorsal graft and supratip graft

Bilateral alar base reductions

Twenty-six months postoperatively, the patient has excellent nasal respiration. On frontal view, her nose is straight, and the left upper lateral cartilage collapse has been corrected. On lateral view, she has a straight dorsum, increased projection, and increased rotation. The basal view reveals a straight, midline columella and supported lateral walls.

This 43-year-old woman requested correction of her nasal deformity and left-sided obstruction. The patient had undergone rhinoplasty 25 years earlier and gradually developed pinching and nasal obstruction. On the frontal view, she had a narrow middle vault, a wide, bifid tip, a hanging tip lobule, and retracted alae. Her skin was very thin, and the outlines of her lateral crura were visible. On lateral view, she had a hanging columella and retracted alae. The basal view revealed a trapezoidal configuration consistent with her wide tip.

Surgical Plan

Significant grafting material was required to correct this patient's problems. Costal cartilage was harvested from the right side of the chest. Correction of the hanging columella required setting back the medial crura and suturing them to the caudal septum. This maneuver lifted the columella and improved the alar-columellar relationship. Complete correction of her deformity required dissecting the lateral crura from the vestibular skin, placement of lateral crural strut grafts, and repositioning into caudal pockets. This maneuver pulled both alae caudally into a more favorable position. Longer lateral crural strut grafts were needed to bring the ala down to the proper level. Additionally, alar rim grafts were placed to increase her nostril symmetry. A small dorsal graft was placed to provide proper dorsal alignment. Perichondrium was placed over the domes to camouflage any tip asymmetries.

Nasal

Lower lateral cartilage

Septum

Lateral

Lower lateral cartilage

Upper and lower lateral cartilages

Surgical Steps

Right inframammary incision and seventh rib harvest

Inverted-V midcolumnellar incision connected to bilateral marginal incisions

Open septoplasty and remaining septal cartilage harvest

Tongue-in-groove setback of medial crura onto caudal septum

Bilateral lateral crural strut grafts, dome sutures, and lateral crura caudal repositioning

Bilateral alar rim grafts

Two layers of perichondrium placed over domes

Septal cartilage dorsal graft

Bilateral alar batten grafts

Thirty-four months postoperatively, the patient has appropriate dorsal width, a refined tip, and correction of her alar retraction and hanging tip lobule. On lateral view, she has a shorter nose with less columellar show and a more appropriate alar-columellar relationship. The basal view shows symmetrical nostrils and a triangular shape.

Concluding Thoughts

Refinement of the nasal tip requires control of nasal tip position and shape of the lower lateral cartilages. Stabilizing the nasal base provides a foundation for the tip modification. Once the nasal base is stabilized, the nasal tip cartilage can be modified using dome sutures, cephalic trim, and cartilage grafting. Some of the more common types of grafting include lateral crural strut grafts, alar rim grafts, and tip grafts. Using these grafts, the tip structures can be stabilized and the domes modified. Projection can be controlled using columellar struts, caudal extension grafts, and tip grafts. Use of cartilage grafting for tip contouring minimizes the need for reduction, which can weaken the tip structures, resulting in pinching and collapse. The structural approach to nasal tip refinement provides excellent long-term outcomes and minimizes the potential for tip deformity.

Clinical Caveats

Tip grafting is an integral component of nasal tip contouring.

Indications for tip grafting include increasing tip projection, prevention of post-operative loss of tip projection, nasal lengthening, straightening tip deviations, and correction of cephalically malpositioned lower lateral crura.

Important components of the tip profile are projection, rotation, the supratip break, the infratip lobular double break, and the alar-columellar relationship.

Important components of the tip frontal view are the tip highlight, symmetry, a smooth tip-alar transition, supratip shadow, and the alar-infratip lobule relationship.

Clear, realistic goals are necessary for a successful surgeon-patient relationship.

Judicious use of computer imaging by the surgeon is critical to establishing realistic patient expectations.

Careful incision design and meticulous skin-soft tissue envelope elevation facilitate a successful result.

Nasal base stabilization is a crucial first step for all tip grafting techniques.

Increased projection can be obtained with suture contouring, tip onlay grafts, and shield tip grafts.

Tip rotation can be achieved by suture contouring, caudal septal trimming, lateral crural resection or division and overlay, and fixation to the native or extended caudal septum.

Tip refinement can be improved by trimming the cephalic edge of the lateral crura, suture contouring, onlay and shield tip grafts, or lateral crura repositioning.

Lateral crural strut grafts can refine the tip, reposition the lateral crura, and correct retracted alae.

Alar rim grafts strengthen the external nasal valve and preserve a smooth tip-alar transition.

Close postoperative care and follow-up is important to recognize asymmetries and improve one's techniques.

CHAPTER 57

Secondary Rhinoplasty

GILBERT C. AIACH, OLIVIER F. GERBAULT,
MARTIN H. KELLY

In primary rhinoplasty, the surgeon is faced with numerous anatomic variations of the underlying skeleton as well as variable qualities of the soft tissue cover and the dynamics of the nose. Even if the surgeon manages to exert a positive influence over healing, complete control over the healing process after rhinoplasty is not possible and may alter the outcome after months and even years. Thus it is not surprising to observe defects of varying severity that have resulted from overresection or overcorrection that require a secondary procedure.

Defects observed after primary rhinoplasty are caused principally by these factors:

Errors in judgment: The rhinoplasty may have been technically well done, yet the nose is unbalanced, not fitting with the other components of the face or with the individual's overall appearance.

Technical mistakes: These vary in extent and can lead to distortion of the anatomy, asymmetry of the osteocartilaginous skeleton, and scarring soft tissue. This makes the dissection planes difficult to differentiate and affects the aesthetics and function of the nose.

Unpredicted poor results: In some cases, the planned correction is successfully executed, the surgeon is satisfied with the immediate result, and no apparent technical error occurred, yet the outcome is still suboptimal.

Secondary problems can be classified as minor or major defects.

MINOR DEFECTS Minor defects occur frequently, in 5% to 20% of cases, as assessed by the surgeon. These defects are often accepted by patients who are satisfied with their overall improvement. Some patients with unreasonable expectations may exaggerate minor defects, asymmetries, and prominences. These patients may complain of palpable imperfections. A frequent example is a small deviation of the dorsum or a minute asymmetry of the nostrils that is seldom noted before the operation but is immediately reported by the patient postoperatively. Slight asymmetry of the nasal tip that can be caused by retraction of soft tissue cover may follow the healing process.

MAJOR DEFECTS Over the past two decades, surgeons have become more conservative in their technical approach to rhinoplasty. Better teaching through videos, live surgery, rhinoplasty courses, numerous books, and the use of the open approach have decreased the severity of postrhinoplasty problems. Nevertheless, major defects still occur. These defects may result from excessive and asymmetrical resections or from a failure to understand the importance of the soft tissue environment, the dynamics of the nose, and, of crucial importance, the quality of support of the tip, alae, and middle vault, which have often been damaged.

Most often, major secondary defects are observed in noses that look unnatural and were operated on because of certain frequently encountered features. For example, as seen in this patient, the nasofrontal angle was underresected and the dorsum overreduced, leading to a shortened nose with a round, underprojected tip. In addition, the airway was compromised and internal and external valve function was altered. These defects were corrected through secondary rhinoplasty.

Anatomic and Technical Challenges Posed by Reoperative Surgery

Difficulties encountered during secondary rhinoplasty depend on the degree of nasal shortening, the extent and location of the bony and cartilaginous resections, the condition of the remaining cartilages, the medial crural support, and the suppleness and thickness of the skin cover.

Soft tissues can be scarred and adherent to the osteocartilaginous skeleton as a result of aggressive surgery on the muscular and subcutaneous layers or aggressive defatting. The cutaneous layers may be adherent to the mucosal lining when cartilaginous resections have been excessive. A lack of suppleness of the nostrils increases the difficulty of the exposure.

In patients with thick skin, certain defects can be masked by the thickness of the cover that cannot be thinned out. The most that one can expect in such instances is only moderate improvement, justifying preoperative preparation of the skin by a dermatologist. Limited dissection and placement of the dorsal and tip grafts are recommended to augment rather than reduce the nose. Dead space should also be eliminated.

The thin skin on the nasal tip and lateral aspect of the radix, where soft tissues become thinner toward the eyelid, is unforgiving. Thus the difficulties vary from case to case, and problems can exist at the level of the covering tissues, mucosa, and osteocartilaginous skeleton during the reconstruction.

The Reoperative Rhinoplasty Patient

The psychological profile of a patient undergoing multiple rhinoplasty operations is a key issue. Whereas primary rhinoplasty patients have not been sensitized by a disappointing result, secondary rhinoplasty patients are well aware of the risks of surgery and will frequently ask only for an improvement. As they recall the pitfalls of the first procedure, some may simply request restoration of their original form and function.

One must be careful when a patient's expectations are very high but the defect is significant and the outcome unpredictable. In major defects with excessive scarring, minor surgery is recommended, with placement of a dorsal onlay and alar graft using an endonasal approach with limited dissection.

Despite significant improvement from the primary rhinoplasty, some patients may still present with minor defects; they express confidence in their first surgeon but request further revision. The surgeon must be wary of unhappy patients who complain of very minor defects and expect perfection, or those who present with more significant defects and make disparaging statements regarding their previous surgeon. Sometimes such patients have consulted many experts, and their expectations may be too high.

Preoperative Assessment

Examination

It is important to take a detailed history and closely examine photographs and reports or worksheets of previous surgeries.

Worksheets accurately detailing the position, amount of resection, and grafts (see p. 2027) are very useful. This combination of information helps the surgeon to appraise the original deformities and understand how they were treated, whether the septum or other sites were harvested, and if any complications occurred. Examination of the nose should be conducted in the same manner as in a primary case. The

Commentary and Criticism:

soft tissues should be inspected and palpated to evaluate their condition and the presence of scarring in all areas.

Examination should proceed from the radix to the tip, assessing the position and projection of the radix, projection of the dorsum, and, by very meticulous inspection and palpation, any minor asymmetry of the bony and middle vault. The tip, alae, and middle vault supports are evaluated, as are alar configuration and symmetry, the alar-columellar relationship, and the nasolabial angle.

Endonasal examination may reveal septal deformities, external and/or internal valve collapse, perforations, and synechia. To determine whether the septum has been harvested, the surgeon can gently palpate the septum on one side with a smooth-tipped instrument while observing the other side with the aid of a headlight. If the septum has been harvested, a softness in the harvested area will be evident on the other side.

Consent

Obtaining informed consent from patients for revision or secondary rhinoplasty focuses more on gaining their trust than on securing their signature on an exhaustive list of potential complications. The simple statement, “There are no guarantees,” succinctly summarizes the requisite degree of understanding. A minimum of two consultations is necessary, in which the same message is communicated after a thorough explanation of the potential pitfalls of further surgery. The goal of the consent process is to allow patients to understand that they have an active, participatory role in what is essentially a journey back from a less than ideal result toward an aesthetic and functioning nose. The patient and the surgeon should make the journey as a team, and any problems encountered along the way are best dealt with as a team. Some problems can be anticipated, such as prolonged edema; some are unfortunate and unforeseen, such as infection or bleeding. Finally, a potentially hostile outcome between an unhappy patient and a defensive surgeon is more likely to be avoided by a close, caring relationship than by the patient’s being presented with an overly long and impenetrable consent form.

Secondary rhinoplasty is more demanding from the surgeon’s perspective, and the requisite few millimeters of form are more difficult to obtain in any direction. It is tempting for a confident nasal surgeon to condemn previous interventions as clumsy, decry the previous surgeon as inept, and promise great improvements. Such an approach, however, is ill advised. During consultation before the procedure, it better serves the surgeon’s goals to underplay the chances of a wonderful result. This will imbue the patient with a sense of wonderment if things go well—and lead at worst to resigned acceptance if they do not.

Preoperative Planning

Timing of Reoperative Surgery

Many early problems such as slight asymmetry, tip bulbousness, and lack of definition may resolve in the months following surgery. During this healing period, the patient needs good support from the surgeon. It is usual to perform a revision after 1 year, but a very early surgery may occasionally be performed during the first week if a severe defect can be quickly corrected. Examples include the removal of a displaced graft or correction of an overshortened nose by reduction of the caudal septum and nasal spine.

A minor defect such as a visible dorsal prominence can be rasped or shaved after a few months with the patient under local anesthesia with the use of a short intranasal incision and narrow instruments. Correction of secondary nasal tip deformities and thick or scarred soft tissues should be performed at least 1 year after the primary procedure.

Surgical Technique

The surgical approach depends on the surgeon's preferences. No single approach or technique is the sole correct one for performing primary or secondary rhinoplasty; it depends on the indications. The technique selected will also depend on the difficulties encountered, including unforeseen ones.

Intranasal Approach

An intranasal approach can be performed for minor defects, such as a dorsal prominence or tiny depression, nostrils of normal size and suppleness, and defects limited to the dorsum without significant asymmetry. A single pocket can be developed with accuracy through an intercartilaginous incision and a graft, bony or cartilaginous, can be inserted.

A transcartilaginous or intercartilaginous incision can provide adequate exposure for the desired corrections, particularly when the nasal tip is symmetrical and does not constitute a major problem. However, the surgeon should not hesitate to shift to the open approach if any difficulty is encountered or if the exposure does not permit adequate correction.

External Approach

We use the external approach in more than 90% of our secondary procedures. With the transcolumellar external approach, a better anatomic assessment can be made of the deformities and supportive structures. It provides easy access to the septum and usually makes harvesting septal cartilage possible, even when septal surgery has previously been performed.

The external approach also facilitates corrections that can be achieved by judicious resections, suture techniques, and reconstruction of the cartilaginous framework and support with accurately fixated grafts.

INCISIONS A transverse columellar incision is placed at the narrowest part of the columella; the incision can be placed at the level of the base of the columella in the labiocolumellar crease when the columella is short with narrow columellar footplates. The extent of soft tissue elevation should be carried out according to soft tissue conditions. The dissection should be less extensive in overly thick skin and in patients with scarred, rigid soft tissues.

A transcolumellar incision is usually indicated for difficult cases in which the patient has small nostrils, a skin cover lacking suppleness, and major defects of the nasal tip. In multioperated patients or those who have undergone several transcolumellar-approach procedures (this is becoming more frequent), dissection of overly scarred nasal tip and columellar soft tissues is still very difficult. Doing so may worsen the scarring when there is thin, adherent soft tissue cover. An endonasal approach or a midsagittal columellar incision may be the last resort, which allows limited maneuvers but permits adequate and accurate placement of grafts.

The midline columellar approach has been used for decades, most often for correction of secondary cleft lip noses and multioperated noses. However, secondary cleft lip noses can often be considered as secondary multioperated noses with nasal tip deformities and significant scarring. The incision is usually placed in the midline of the infratip segment; its length is usually 4 to 6 mm, depending on the deformities. It can be extended anteriorly if the surgeon plans to work on the nasal tip, or posteriorly to introduce a large graft.

A tip graft is inserted through a short sagittal midcolumnar incision. Dissection can usually be performed easily and quickly. Because of the shortness of this incisional approach, maneuvers must be very carefully executed with narrow instruments and attention to the integrity of the skin edges. Narrow scissors, an elevator, and a Beaver blade protected with a strip can be used to dissect heavily scarred soft tissues when there is no more dissection plane.

Local anesthesia of the lobule alone frequently suffices and is less distressing than vestibular or total nasal infiltration. The postoperative course is reduced in time and magnitude. Such advantages allow the surgeon to minimize the significance of minor touchups (particularly our own retouches) in terms of duration and ease and represent less pain and lower hospital costs for the patient.

Dissection can be performed over and between the domes and extended laterally to the alae and upward to the dorsum. If the incision is extended posteriorly to the labiocolumellar junction, it may provide access to the membranous septum and straightforward placement of graft within the membranous septum and columella for correction of a retracted columella. A columellar strut can easily be placed through this approach, and tip projection can be augmented with a graft slightly longer than the pocket. The tip lobule can be grafted with a single or multilayered graft. For intratip and infracolumellar grafts, the skin should be conservatively dissected laterally to avoid tension and the risk of disruption or necrosis.

The best indications for this approach are heavily scarred or thick soft tissue cover with narrow nostrils that do not permit an endonasal approach, or in cases in which a transcolumellar approach is not desirable because of the presence of overscarring of the endonasal lining. Precise undermining can be performed to place a dorsal and tip graft, producing less postoperative edema.

The limitation of this approach is the short incision length, which does not allow the same degree of exposure and precise cartilage manipulations that more extensive dissection techniques permit.

Secondary Problems

Moderate and Minor Defects

Minor defects most often involve a cartilaginous or bony projection problem, a slight asymmetry or deviation, or a minor depression. Such defects may appear after several months, when the edema has completely resolved. Correction is usually simple and rapid and in most instances can be carried out with the patient under local anesthesia. A bony or septal prominence can be trimmed or rasped using a narrow 3 or 4 mm rasp, which, after an endonasal puncture incision, permits direct access to the prominence without preliminary undermining. A bony projection can be easily rasped, as can a slight excess of the rigid dorsal border of the septum.

The danger in correcting these tiny defects lies in making the problem worse. Rasping a graft that has been bruised in the previous surgery or rasping a thin bone graft placed under thin skin may displace fragments of the graft and create more pronounced defects.

In this patient, a radix defect is evident on the lateral aspect, where the soft tissue thickness decreases. This slight dorsal prominence is shaved using a narrow rasp.

A small depression can be corrected by filling the area with crushed cartilage graft, preferably harvested from the septum. The crushed cartilage can be introduced after minimal tunneling. Diced cartilage is the preferred method when large defects must be corrected. Moreover, this allows a long-lasting correction.

Very finely diced cartilage can also be injected with a 1 cc Luer-Lok syringe and a 16- or 17-gauge injection cannula (the type used for fat grafting). Any kind of cartilage can be used, but the most practical procedure is to anesthetize the area with a local anesthetic, harvest concha, dice it, and reinject it through a small stab incision.

Small defects can also easily be corrected with fillers. The most frequently used fillers for this purpose are hyaluronic acid gels and Radiesse, which consists of calcium hydroxylapatite microspheres suspended in a sodium carboxymethylcellulose gel.

Hyaluronic acid is used preferentially in thin skin locations where a deep injection cannot be performed, such as the columella, and the tip in thin-skinned patients. Radiesse may be used in the radix, dorsum, supratip, and premaxilla. Early inflammatory reactions, foreign body granulomas, and allergic reactions are very rare with these fillers. Hyaluronic acid lasts 8 to 12 months; Radiesse lasts 2 to 3 years. It must be injected deep, on the top of the bone or cartilage. Caution is necessary when correcting an inverted-V deformity: the filler must not be injected close to the mucosa to avoid infection and decrease the risk of granuloma formation.

Discrete deviations are difficult to correct; they are often caused by a residual cartilaginous deviation or asymmetrical resections. It is often easier, and preferable, to correct them by limited procedures rather than carry out wide undermining and osteotomies, because there is a risk of incomplete correction and other sequelae. Placing camouflage grafts on the side opposite the deviation is sometimes a simpler and more effective solution.

Radix Defects

The position of the radix is crucial to a harmonious result. Radix projection and position influence the nasal length and nasofacial angle. The ideal radix position is between the supratarsal fold and the eyelashes and can vary from 10 to 12 mm (when overresection or overgrafting is being corrected).

Projection of the radix is 4 to 6 mm deep to the glabella (as noted by Guyuron) and 10 to 11 mm from the corneal plane (documented by Byrd). Projection of the radix can make a nose look longer, particularly if there is no clear delineation between the nose and the forehead, as with a Greek nose.

High Radix: Underresection

A high radix is frequently observed after a rhinoplasty. It is caused by underresection of the bony radix, which is difficult to correct because of the dense bony radix and the thick muscular layer (the procerus muscle).

Reduction of the radix is not an easy task. Bony radix reduction can be prepared by using a 2 or 3 mm osteotome introduced percutaneously to create a trench above the area to be resected. This facilitates resection with a beveled, well-sharpened osteotome; the surface of the bevel is angled to allow the osteotome to be directed at a better angle.

Adequate deepening of the radix is essential when a dorsal graft extends to the radix. Before a cartilage graft is placed, deepening should be limited to 1 mm. When using a bone graft, the surgeon needs to maintain sufficient thickness of the cephalic end of the graft to prevent a bony fracture. On the other end, the radix should be well prepared for a bony union and sufficiently deepened to prevent a shallow radix.

Resection of the procerus allows moderate (1 to 2 mm) deepening of the radix. The muscle is resected with scissors or a rasp. A vasoconstrictor-impregnated gauze pad is then placed in the radix area to decrease bleeding. This approach should be avoided in thin-skinned patients.

Excessive Bony Resection

Overresection of a dorsal hump resulting from use of an osteotome with the wrong orientation may create a high middorsal notch with a high radix or dorsal saddling, including the nasion area, which has been overresected, causing the glabella and nasal base to appear more prominent.

It is important before any radix reduction to palpate and pinch the soft tissue of the radix to assess thickness (average 7.5 mm) and laxity. Despite overreduction of the bony radix, an excess of soft tissue of the radix may be present, creating fullness and a wider appearance of the intercanthal distance. This is a result of poor soft tissue response after bony reduction.

The average soft tissue response (contraction and redraping) in the radix area is 25%, resulting from two factors: (1) the thickness and laxity of the covering soft tissues, and (2) the limitation of redraping laterally by the fixed inner canthal points.

Correction of a radix defect can be performed with cartilaginous grafts, deep temporal fascia, fillers, or diced cartilage. The cartilaginous graft is the benchmark procedure for correcting an overresected radix. The best adapted grafts are septal or lower lateral crural grafts. They are very effective, but their main drawbacks are edge visibility and displacement. To avoid those problems, undermining over the radix area must be limited on the lateral aspects. The sides of the grafts are beveled, the grafts are weakened (with incisions or slight crushing), and two percutaneous through-stitches are performed. Grafts can be superimposed if the radix needs more than 2 or 3 mm of augmentation.

Deep temporal fascia is very easy to harvest, and the resulting 3 cm scar in the temporal scalp is inconspicuous. This fascia can be folded on itself for more projection. Two percutaneous through-stitches are also used. Edge visibility is never an issue with the use of this fascia, but swelling is more prolonged than with a cartilaginous graft.

Acellular dermal matrix products such as AlloDerm can be used in place of deep temporal fascia, but partial resorption may sometimes occur for such allogenic materials.

Fillers are very practical for correcting radix defects. Radiesse may be more appropriate than hyaluronic acid, because it lasts longer. If hyaluronic acid is selected, a highly reticulated form is used (Juvéderm Ultra 4, Perlane). The injection can be performed in the office, and the resultant correction is immediate.

Diced cartilage is very useful in this location and produces a long-lasting result. This procedure can be performed with the use of a local anesthetic in the office.

Saddle Nose Deformities and Flat Nose

Saddle Nose

Saddle nose deformity can involve the entire dorsum from the root to the supratip region or only the lower dorsum, causing a “hatchet stroke” deformity with a more or less noticeable hump above it. Overresection of the dorsum with an osteotome, including nasal bone, upper lateral cartilage, and the dorsal edge of the septum, causes saddle nose, with middle vault collapse. However, saddling may also result from an underlying septal cartilage fracture or weakness, from collapse of the dorsal edge of the septum after a submucosal resection of the septum, or from harvesting too close to the dorsal edge of the septum.

Saddle nose deformity is commonly considered to affect the nasal width, length, and nasal valves. Posttraumatic effects may include broadened nasal width, with a flat appearance of the nasal vault and a more pronounced nasal base. Tip and columellar support may have been damaged by overresection of the nasal spine and septal caudal border, causing a retracted columella; these supports can be assessed by pressing backward on the nasal tip. Supratip saddling may also occur after overresection of the lower dorsum or a large septal perforation.

Saddle nose deformity from the radix to the supratip area after aggressive dorsal resection of the hump is illustrated on the left. Deformity of the lower dorsum causing a hatchet-stroke deformity with a more or less noticeable hump above it (true or false hump, respectively) is shown on the right.

Surgical correction of a saddle deformity consists of restoring the damaged supports and filling the defects by various means:

Repositioning of asymmetrical and displaced structures with restoration of the original septal height.

Reconstruction of the dorsum with single or multilayered cartilage, with diced cartilage wrapped in fascia, or, rarely, with bone grafts, depending on the magnitude of the deformity, the availability of cartilage, the quality of the recipient beveled graft, and the skin. Septal cartilage is best for augmenting the dorsum. Conchal cartilage will not provide a sufficiently long fragment, and its curvature is less suitable for the dorsum. The external portion of the concha may provide a long (3 cm) graft that can be flattened by a superficial partial-depth incisions followed by light bruising.

A longer graft can be obtained by overlapping two grafts as tandem grafts. But if support grafts must be used and if the septum is not of good quality (for instance, because it has been fractured, bent, or partially harvested previously), costal cartilage is the best option. Rib grafts allow the use of long, straight, solid pieces of cartilage for support and provide a sufficient quantity of cartilage to be diced and wrapped in the deep temporal fascia for dorsal augmentation. The *diced cartilage and fascia* (DCF) technique avoids the use of a monobloc cartilage trimmed from the costal cartilage, with its own risk of bending, and obviates the need for a K-wire to stabilize the graft to decrease the risk of bending.

After an extramucosal dissection, the upper lateral cartilages are separated from the anterior septal border. An anterior septal deviation can then be corrected by cartilaginous incisions or cartilaginous struts to reinforce the septal buttress and to camouflage a deviation. The nasofrontal angle should be slightly deepened when the dorsal graft extends toward the radix. Medial and lateral osteotomies allow correction of an asymmetrical, flat, wide nose, but the surgeon must keep in mind that saddling creates the illusion of flatness and, after dorsal augmentation, the nose may appear less broad. Secondary osteotomies to correct a broad or asymmetrical bony vault are best achieved by external percutaneous osteotomies. Two-millimeter perforations allow the surgeon to trace a pattern along the desired osteotomy line, followed by gentle pressure only when all bony struts have been securely broken. This method also allows asymmetrical osteotomies to be safely performed to correct nasal bones that were malpositioned at the primary surgery.

The endonasal approach is sufficient if the dorsal deformity is isolated. When other defects are present, notably at the level of the nasal tip, a transcolumellar approach is used, particularly for a difficult nasal tip reconstruction.

ASYMMETRICAL RECIPIENT GRAFT BED An asymmetrical recipient graft bed is quite common in saddle nose deformity because of previously undetected and untreated asymmetry, asymmetrical cartilaginous hump resection, uneven osteotomies, or multifragmented bone during hump resection.

An asymmetrical graft can sometimes be used to correct an asymmetrical recipient graft bed, as in this patient, who complained of a dorsal depression with asymmetry and impaired breathing. She desired a longer nose with a straight dorsum. On frontal view, on the right side, one can see collapse of the lateral bony and middle vault, which produced the optical illusion of a deviation. The defect was more discernible on the bone (with a vertical depression) than on the middle vault. The lateral view shows a slightly retrousse nose and an open nasolabial angle greater than 110 degrees. The basal view shows that the left dome was higher than the right and that there was a slight deviation on the left. The oblique view shows saddling of the upper dorsum. On forced inspiration, there was a discernible collapse at the posterior junction of the lateral crura and upper lateral cartilages.

A transcolumellar approach was used to correct the problem. After skeletonization, the radix was moderately freshened with an osteotome to obtain a radix recipient graft as flat as possible. The septum was approached dorsally, and major harvesting of cartilage and thin bone (vomer and perpendicular plate) was performed.

Reconstruction was achieved by placing grafts in different areas of the nose. Because the upper dorsum was quite asymmetrical, an asymmetrical dorsal graft was prepared. The main graft was bruised and two narrow grafts were placed at the under-surface of the right edge of the main graft to fill in the lateral depression. A small bony graft was placed laterally on the right side of the bony vault. The caudal end of the graft was fixed to the dorsum. Two flat, thin, bony fragments from the septum were positioned in the weak area at the upper and lower lateral cartilage junction.

A columellar strut and an onlay graft were placed to strengthen the columella and improve the tip definition and contour. No osteotomy was performed. The patient is shown 13 months postoperatively.

DICED CARTILAGE Diced cartilage rolled up in fascia (DCF) is the most appropriate technique for correction of saddle nose deformity. It consists of tailoring a composite graft of pieces of diced cartilage and wrapped in a layer of deep temporal aponeurosis. This initially malleable graft allows an effective dorsum augmentation (1 to 10 mm), which is adjustable until the end of the operation and even postoperatively. It can easily be introduced through a closed or open approach.

This graft is applicable to all primary and secondary augmentation rhinoplasties. However, the elective indications are for secondary augmentation rhinoplasties with cartilaginous donor site depletion or when cartilaginous grafts are of poor quality (because they are of insufficient length or are multifragmented), or when the recipient bed is uneven or asymmetrical. In this last situation, the DCF is prefabricated on the back table to fit the defect. After positioning the DCF on the dorsum, it is precisely and delicately molded onto the defect to fit the uneven recipient site. In all cases, the DCF is positioned at the end of the operation, after all the septal work has been done and all support grafts have been sutured.

This patient had undergone three previous rhinoplasties through an endonasal approach to correct a wide, overprojected nose with a hump and wide nasal tip. Cartilage from one ear was harvested on the first revision surgery, and from the other ear for the second revision. The patient had not been able to breathe well since her first surgery. The frontal preoperative view shows an inverted-V deformity with a left nasal bone that was too lateral. The tip was too wide, bifid, and asymmetrical, and the nostrils were too visible because of alar retraction. On basal view the upper lateral cartilages were collapsed into the nostrils because the previous hump removal was performed without reconstruction of the internal valve.

The lateral and oblique views show an obvious lack of tip projection, tip bifidity, and alar retraction. A ninth costal cartilage was harvested; then a 4 by 4 cm deep temporal aponeurosis was harvested for the DCF.

A transcolumellar approach was planned. The intraoperative view on p. 2044 shows a complete transfixion of both lateral crura. The lower lateral cartilage had been overresected, and there was marked flaring of the middle crura. The central cartilage was to be used for the two spreader grafts, the columellar strut, and the tip graft. Slightly naturally bent slices of outer rib cartilage were used as alar batten grafts, extending caudally to lower the alar rims.

The remaining cartilage was diced to be used as a DCF. The diced cartilage was introduced in a 1 cc tuberculin syringe and compacted. The deep temporal aponeurosis was sutured around the syringe, and the hub of the syringe was cut. The distal part of the DCF was closed and the diced cartilage was injected in the aponeurosis tube. The DCF was then carefully molded on the back table.

Operative view after opening

Before closure

Tip graft and alar rim grafts

After approximating the domes with an interdomal suture, a columellar strut and shield graft was placed, and alar batten grafts were sutured to the vestibular skin and the cut end of the lateral crura. The aponeurosis tube was inserted on the dorsum at the end of the operation, after the supporting grafts were sutured; it was sutured to the remaining upper lateral cartilage, and its cephalic part was stabilized with two percutaneous stitches.

The patient is seen at 1 year postoperatively. The aesthetic dorsal lines are restored, the tip is smooth, and the alar notching is corrected.

Flat Nose

A flat nose often results from trauma or a previous surgery in which the caudal septum and the lower lateral cartilages have been damaged or overresected, with significant loss of the tip supports. On examination, the interalar base distance appears wide in respect to the length of the columella. The nasal tip is easily depressed, with poor columellar and septal support, and on palpation alar cartilages appear weak and soft. A dorsal depression and retracted columella are caused by overresection of the dorsal septum or by a large septal perforation extending anteriorly.

Correction of flat noses involves strengthening the anterior and caudal buttress and the tip and columellar supports and restoration of the septal deformity. In a moderately flat dorsum and nasal tip, extended spreader grafts are sutured to a wide columellar strut to provide a solid L-shaped strut. Then the medial and middle crura are sutured caudally to the columellar strut. It is sometimes necessary to conceal dorsal irregularities with deep temporal fascia or crushed cartilage. In a markedly flat dorsum and nasal tip, a dorsal graft and a long bony or costal cartilaginous L-shaped strut may be placed. This type of reconstruction is rigid and often does not look natural. Its aesthetic appearance can be improved by the use of a DCF on the dorsal part and by a columellar strut with the medial and middle crura sutured to it on the caudal part. If a costal or bone graft is used in the columella, it can be fixed to the nasal spine. The medial crura are then advanced on the strut and transfixion sutures are placed through previously made perforations on the strut.

This patient had undergone two previous rhinoplasties and septoplasty. She presented with a flat nasal base, short columella, and severe loss of nasal tip supports. On frontal view, there was a wide dorsum and a large interalar base distance with a flat nasal tip. On basal view, the scar of a previous transcolumellar incision was obvious; the columella was very short, with pseudoalar flaring caused by the severe loss of tip supports. Endonasal examination showed a large anterior septal perforation, precluding any septal harvesting.

The main problem was the loss of columellar support, which had to be reconstructed with a stiff columellar strut.

The conchae were harvested using a retroauricular approach. A transcolumellar approach was performed, revealing the poor laxity of the alar cartilages.

A pocket was developed on the dorsum for placement of a dorsal graft. The columella and nasal tip were reconstructed with a fleur-de-lis graft with the two lateral edges of the conchae. Because the cartilage was very soft, a rigid 0.5 mm thick battens of polydioxanone (PDS) plate (15 by 5 mm) was placed between the two cartilages and sutured to them to provide sufficient stiffness to the grafts. The divergent anterior extensions of the grafts were positioned on the top of the domes and sutured to the lateral crura. A single-layer graft was placed on the dorsum, and lateral and medial osteotomies were performed.

The patient is shown 12 months postoperatively. The PDS plate has been resorbed and replaced by connective tissue. The plate was used as a temporary scaffold to provide a stiff columellar support during the early stages of healing.

Graft Defects

Problems include defects that occur after placement of grafts in the radix, dorsum, or tip; in addition, secondary rhinoplasty in a graft-depleted patient presents a challenge. Grafting techniques are frequently used to augment, contour, balance, and reconstruct the skeletal structures that produce the nose's function and aesthetics. However, as in every technique, there are advantages and drawbacks, and various defects or complications may be seen during and after grafting. Besides the difficulties that follow graft placement, the surgeon may encounter the complications inherent in the harvesting process, such as these:

- Auricular deformity
- Retroauricular keloids
- Septal perforations
- Creation of a supratip hatchet defect after a loss of septal support
- Fracture of the perpendicular plate of the ethmoid after aggressive resection with forced twisting motions that may cause cerebrospinal fluid leakage
- Pneumothorax after rib graft harvesting

The problems that occur most frequently after placement of grafts are seen when using “visible graft” in the radix area, dorsum, and tip. They include undergrafting or overgrafting, prominence with graft visibility, asymmetry, and irregularities caused by warping of the graft; graft displacement; and a poorly prepared recipient bed.

An asymmetrical recipient graft bed will automatically cause displacement and asymmetry. Infection is rare, but it may occur with conchal cartilage and in severely scarred or thick, soft tissues; resorption may be seen, mostly after bone grafting, and may follow an infection. Skin discoloration and telangiectasis are more frequent after several surgeries in a patient with thin or scarred soft tissues. The incidence of such defects can be decreased by scrupulous attention to and management of the successive steps of grafting.

Radix Graft Defects

Radix defects may be observed after using grafts that have not been modeled by bruising, that are too wide, and that have edges that have not been beveled and do not feather with the adjacent areas. Visibility of a radix graft usually occurs laterally and caudally in areas where soft tissues are thin.

Soft tissue thickness varies over the bony skeleton; it is thinner over the rhinion (2 to 3 mm), where a step off may be observed when the graft ends at the level of the rhinion. Soft tissue thickens (7 to 9 mm) as one approaches the midline of the nose, but thickness progressively diminishes laterally toward the inner canthi. This explains why defects of radix grafts are seldom observed on the midline and are more frequent laterally and caudally.

Radix defects can be limited by careful preparation of the recipient graft bed with moderate, symmetrical undermining at the level of the radix, followed by light rasping to remove the soft tissue remaining on the periosteum. Bruised narrow grafts should be used, with particular attention to the preparation of the caudal end of the graft, where a smooth continuity with the dorsum should be obtained.

When the radix and upper dorsum are to be grafted, it is sometimes better to use a longer graft that extends from the radix to the supratip after slightly rasping the dorsum. This provides more stability to the graft and decreases the risk of a defect in the rhinion area.

Correction of radix defects is not easy and depends on the type and condition of the graft. The graft can be bone or cartilage (septal, ear, costal). If a septal graft had been placed, it can be rasped with a narrow rasp introduced intranasally. It is risky to rasp an ear cartilage graft or a cartilage that has been bruised. The prominent defect can be punctured percutaneously with a Keith needle if the defect is inconspicuous. In selected cases, a skin incision placed laterally provides a good approach and an easy correction with a narrow rasp and a Beaver blade. The scar will be scarcely visible. If the edge of the graft is visible and the defect is mild, injection of hyaluronic acid around the graft's edge can reduce its visibility.

Bruising should be gentle and incremental. The graft should be checked after each stroke of the hammer to determine whether it has the requisite malleability to conform to the recipient graft bed, maintain its integrity, and not be visible at the skin surface. The best materials to use for radix grafting are the resected cephalic portions of a lateral crus or a bruised septal cartilage. A dorsal graft should be formed into a tilelike shape by bruising or partial-depth incisions.

Dorsal Graft Defects

On the dorsum, besides overgrafting, undergrafting, and wrong positioning of the graft, defects frequently encountered are graft visibility and asymmetry caused by displacement of the graft. One can also observe a lateral depression along the lateral edges of the graft, mostly in patients with thin skin, when the graft has not been modeled by bruising or by longitudinal partial-depth incisions and when the dorsum is narrow.

Grafting the dorsum requires assessment of the shape and volume of the graft. This can be done preoperatively by using modeling paste or perioperatively by using templates of different sizes and shapes. Preparation of the recipient graft bed should be carefully checked by palpation with a wet finger on the skin surface and, if possible, by direct visualization to trim any projection or irregularity that would create an instability or displacement of the graft. If a bone graft is planned, one must flatten the bony dorsum and deepen the radix.

Correction of defects of the dorsum can vary in difficulty. A slight septal cartilaginous or bony prominence can be shaved. If asymmetry is severe, balanced resections and additional grafts will be needed. When additional grafts are required on the dorsum, it is better to insert the new graft at the undersurface of the main graft when the dorsal contour is correct. In some situations, it is better to remove the graft and replace it after better preparing the recipient graft bed and suture fixation.

This patient had undergone two previous rhinoplasties that resulted in an overresected middle third of the dorsum and fullness of the radix and supratip. The infratip lobule had an increased angle of rotation. The alae were retracted and a hanging columella was evident. In addition to flatness of the middorsum (seen on the frontal view), the nasal base had a wide interdomal distance. The domes were markedly visible (more on the right side) in relation to a section of the lateral genu of the domes.

With a transfixing incision, the overexposed caudal septum (8 mm in height) was resected. The quadrangular septum was approached through this incision and major harvesting was performed, followed by placement of quilting sutures in the mucosal flaps with 5-0 Vicryl Rapide.

The alar cartilages demonstrated the asymmetry resulting from previous resections. The radix was deepened with a beveled osteotome. The dorsum was rasped slightly to remove soft tissue, and the caudal borders of the medial crura were trimmed by 2 mm to improve the columellar-alar relationship.

Reconstruction was achieved with a fishtail dorsal graft. The caudal end of the graft was notched to saddle the anterior septal border. The two parts of the tail were then folded over the lateral aspect of the dorsal septal border and sutured to it. This suture can include the anterior borders of the upper lateral cartilages. Such a graft may provide both an aesthetic and functional effect by leveraging the skin cover. After suturing, the dorsum was checked with a wet finger. Any excess can be shaved, or the notch can be extended upward. A percutaneous suture was placed in the upper portion of the graft, and the cut ends of the domes were approximated in the midline with an interdomal suture.

Alar grafts were prepared by splicing a thick septal fragment into two 0.5 mm thick batten grafts. These grafts were sutured to the remaining lateral portion of the domes. A bruised infratip shield graft was placed to improve the contour of the tip and infratip. No osteotomies were performed.

The patient is shown 19 months postoperatively.

Tip Graft Defects

Numerous defects occur in the tip from overgrafting or undergrafting, malposition, displacement, and graft visibility, which usually in thin-skinned patients.

Prevention

The risks that these defects will occur are limited with an open approach.

To correct a defect of the nasal tip, the surgeon should prepare the recipient site accurately by equalizing the height of the domes and the caudal borders of the intermediate and medial crura before placing an onlay or infratip graft. Suture fixation can prevent displacement.

For very thin-skinned patients, cartilaginous sutures should always be considered to treat the tip problems before using any visible graft. Capping the cartilage with deep temporal aponeurosis or with perichondrium or periosteum decreases the risk of early or late visibility.

Correction

Inconspicuous defects can be corrected with an infracartilaginous incision for shaving a prominence of the graft or adding a thin graft to correct an asymmetry. A sagittal midcolumellar incision can sometimes be used, especially when tip tissues are fibrous after several rhinoplasties. A transcolumellar approach constitutes the best approach for correcting tip defects. Sometimes the whole graft must be removed and discarded when it is not usable. Otherwise, the graft can be reshaped if it is large and strong enough, or it can be covered with deep temporal fascia in thin skin.

Graft-Depleted Patients

Usually, part of the septum and at least one concha has already been harvested. It is sometimes possible to harvest more septum if only a small piece has previously been taken. Usually the remaining septal cartilage is behind and above the previous area where the cartilage has been harvested. If both conchae have already been harvested or if a small piece of cartilage is needed, ear cartilage can also be harvested on the scapha or tragus.

Finally, costal cartilage is always usable, and the associated morbidity can be very low with a good technique, but its harvesting is a little more lengthy and tedious. Costal cartilage allows the use of long, straight pieces of cartilage, which is not usually possible using ear cartilage or parts of the septum. Those straight cartilages are first used for the support grafts (spreader grafts, columellar struts, septal extension grafts, alar grafts, or alar rim grafts). Smaller pieces are used for tip grafts, sidewall grafts, and radix grafts. If augmentation is needed, especially dorsum augmentation, the remaining cartilage pieces are diced and used in the DCF technique.

Harvesting septal material is sometimes possible by approaching the septum close to its dorsal edge and dissecting above and behind the scarred area from a previous septoplasty. The ear may provide adequate fragments from the scapha and tragus.

Prevention of Graft Displacement

Preventing or Minimizing Graft Displacement

The following measures are instrumental in preventing or minimizing graft displacement and the effect on contour:

Create an adequately sized graft pocket.

Prepare a flat, symmetrical recipient graft bed and rasp the soft tissues over the skeleton. In the upper dorsum, prepare a solid, flat, bony foundation by rasping; however, it is more difficult in the lower part of the dorsum, where the recipient site is composed of the anterior border of the septum and upper lateral cartilages.

Select a graft that extends down to the supratip to stabilize the upper and caudal portions of the graft. A longer graft avoids a step-off, which can be observed in the transition zone (rhinion area) despite careful beveling of the lower end of the graft.

Use endonasal and percutaneous suture fixation.

Notch the two ends of the graft to create a fishtail shape for additional fixation. This is useful in radix, shield, and dorsal grafts: notching provides more stability by interposition of soft tissues.

After two previous rhinoplasties, this patient complained about several deformities and impaired breathing. On lateral view, she had saddling of the upper dorsum and radix highlighting the volume of tip and supratip. There was an obvious excess of the dorsal septum in the supratip, and the tip was unpleasant with an increased angle of rotation and a retracted ala, mostly on the left side.

On frontal view, there was an inverted-V deformity with disruption of the dorsal lines, and the tip was asymmetrical with a more prominent dome on the right side. On basal view, collapse of the middle vault, asymmetry of the tip, and collapse of the right ala were evident. The footplates of the medial crura were prominent. There was an internal valve dysfunction on both sides and a septovomerine deviation.

The objectives of surgery were to balance this nose by augmenting the upper dorsum, refining the tip symmetry, and improving function and contour. After harvesting the right concha, through a transcolumellar approach skeletonization was performed, revealing the deformities and the weakness of the alar cartilages. The supratip

excess was shaved by 2 mm and the radix freshened with a rasp. Major septal harvesting was carried out, and 2 to 3 mm of caudal septum was resected. Two spreader grafts were placed and the tip was corrected; better symmetry was obtained by dome resection, followed by suturing of the cut ends of the cartilages. The divergent footplates of the medial crura were resected.

A septal columellar strut was positioned within the medial crura to provide better tip support, and cartilage grafts were placed. A thin septal graft was placed on each lateral crus. The configuration, projection, and definition of the tip were improved with an infratip graft of ear cartilage; a buttress graft was positioned between the domes and the cephalic aspect of the shield graft to decrease the angle of rotation. A three-layered dorsal graft composed of vomer, ear cartilage, and septal cartilage was sutured together, and the caudal end of the septal fragment was notched in a fishtail shape with sutures of the two parts of the tail to the adjacent tissues to stabilize the graft. Results are shown 2 years postoperatively.

Guidelines for the Use of Grafts in Secondary Rhinoplasty

Preoperatively, assess the graft's length, width, and thickness using photos and modeling paste.

Never rush when choosing a design from harvested material. Carefully select the best fragment for every area. Assess the priorities if many areas are to be grafted.

Be very economical, because reconstruction often requires a large amount of graft.

During the procedure, use a template or sizers to avoid damaging the graft by repeated handling and insertions.

Middle Vault and Alar Deformities

The role of the lateral cartilaginous wall (the upper lateral cartilage, lateral crus, and soft tissue cover of the middle vault and alar wall) is often overlooked during routine preoperative nasal examination and during surgery. Postoperative deformities of the middle vault and alae are often caused by overresection and misidentification of unfavorable anatomic variants of the cartilages. Other predisposing factors, such as soft tissue cover and the anatomic configuration of nasal bones, may contribute as well. The result may be a narrowing of the middle vault, with an inverted-V deformity and collapse of the internal and external nasal valves.

Middle Vault Deformities

The middle vault is composed of the upper lateral cartilages, septum, and investing soft tissues. Support of the upper lateral cartilage is provided cephalically by a tile-like connection to the inner portion of the solid bony vault and medially by an anatomic and histologic continuity with the widened dorsal edge of the septum. The junction of the septum and the caudal margin of the upper lateral cartilage form the internal valve angle, which is normally 10 to 15 degrees.

After resection of the wide T-shaped extension of the dorsal septum, the middle vault narrows as a result of medial approximation of the free medial edges of the upper lateral cartilages. The degree to which lateral movement occurs depends on the intrinsic stability of the upper lateral cartilage (its shape, elasticity, and size) and soft tissue support, and on the pressure changes to which it is subjected during quiet and forced inspiration. In the absence of a lateral osteotomy of a broad bony vault, there is a high risk of middle vault collapse.

After a lateral osteotomy with a high cephalic fracture, the bony cartilaginous wall becomes mobile and can be moved toward the midline. However, when the nasal bones are convex and the high cephalic fracture is incomplete or too high, the degree of displacement of the bony portion is limited in respect to that of the flexible upper lateral cartilage. When the nasal bone (upper lateral cartilage junction) has been damaged, the upper lateral cartilages have a greater tendency to move inward. It is important to evaluate the length of the nasal bones, because short nasal bones provide less support to the upper lateral cartilages, as well as to assess the condition of the skin and cartilages.

Evaluating Operative Causes of Middle Vault Collapse

Factors that contribute to the weakening of the upper lateral cartilage and increase the potential deformation and collapse include the following:

- Avulsions or lacerations of the upper lateral cartilages as a result of aggressive rasping or excessive resections of these cartilages, causing a depression of the middle third of the nasal pyramid

- An osteotomy that is too high, with excessive resection of the tissue, especially along a large nasal hump

- Preexisting extensive soft tissue undermining

- Neglecting to mobilize and suture the upper lateral cartilages back to the midline after dorsal hump resection

Potential Problems

During preoperative examination, the surgeon observes the lateral walls for external abnormalities. Middle vault collapse may occur when there is a narrow cartilaginous vault, in contrast with a wide bony vault, or when the nasal bones are convex, and a slight demarcation exists between the nasal bones and upper lateral cartilages. Palpation may reveal a convexity at the lower border of the nasal bones that can be followed downward to a noticeable narrowing of the cartilaginous vault.

Endonasal examination may detect an aspiration of the lateral walls of the nose, with or without an alar collapse. The surgeon should look for mucosal scars in the form of synechia or bands, and deviation of the anterior septal border.

A cotton-tipped applicator is used to gently spread the alae from the septum to examine the internal valve for suppleness, integrity, valve angle, and mobility of its lateral border at rest and during forced inspiration.

The inner surface of a large resected hump should be examined to assess the width of the septal T. After lateral osteotomy and medial displacement of the bony carti-

laginous flap, the surgeon can examine the oblique view from right and left and pass a wet finger on the lateral aspect of the dorsum to detect any interruption of the continuity between the upper lateral cartilages or a step-off—the sign of a collapse or weakening of the upper lateral cartilage.

Surgical Correction

Middle vault collapse can be difficult to correct through an endonasal approach, and even more difficult when the nostrils are narrow. The external approach allows good exposure and accurate correction. The normal anatomy of the cartilaginous vault must be recreated; specifically, the septal T must be enlarged and a normal valve angle created.

After an extramucosal dissection has been performed, the mucosal domes can be approximated toward the midline. Various types of grafts may also be used for correction. The role of grafts is not limited to morphologic aspects; they are also used to prevent or correct functional problems. A cartilaginous dorsal graft placed over the dorsum may provide a spreading effect of the upper lateral cartilages by leverage of the soft tissue cover.

A spreader graft, as described by Sheen, can be placed via an endonasal approach in submucosal tunnels on either side of the anterior septal border but the open approach offers more accuracy in positioning and stabilizing the grafts. The spreader grafts should extend from the junction of the nasal bones and upper lateral cartilages to the nasal valve area. Their ends and posterior border should be feathered. Their thickness depends on the importance of the deformities. The caudal portion of the septum usually provides a thick 2 to 3 mm fragment. The surgeon can use a two-layered graft if there are thin fragments. When the septal mucosa has been widely elevated, the spreader grafts must be stabilized with two sutures of 5-0 Vicryl or PDS.

Septal cartilage is the best material for dorsal and spreader grafts. This cartilage can also be bruised and positioned superficially to the upper lateral cartilage to fill in a depression. In severe cases, with overresection of the upper lateral cartilages and collapse, a splay graft (Guyuron) allows a pleasing reconstruction. The splay graft saddles the middle vault with the two lateral portions of the graft being placed submucosally. Some patients complain of increased difficulty on quiet or forced inspiration, often associated with excessive movement of the nasal ala toward the septum (collapse).

Parallel dorsal lines should be obtained after a rhinoplasty (*left*). On the secondary rhinoplasty patient shown on the right, a disruption of these lines is caused by a middle vault collapse, highlighted by a broad bony vault with convexity more evident on the left side.

This patient had several deformities of his nose and difficulties in breathing. On frontal view, there was a broad bony vault. The middle vault was collapsed, with disruption of the dorsal lines, and a deviation with a concavity on the right.

On the oblique and basal views, one could see a concavity of the alar walls that was more significant on the right side, and a narrow tip lobule. Endonasal examination showed a septal deviation and an internal valve dysfunction, both of which caused the breathing impairment.

After harvesting the conchae through a retroauricular approach, an open approach was selected, exposing the deformities of the alar cartilages. The dorsum was slightly rasped and the radix lowered with a beveled osteotome. The septum was approached via the dorsal edge, and septal material was harvested. The deviation was corrected by repositioning the caudal septum in the midline. The nasal spine was conservatively resected, and the caudal septum was sutured to the soft tissues surrounding the nasal spine.

Endonasal and percutaneous medial osteotomies and endonasal lateral osteotomies were performed. Two spreader grafts were positioned at different levels, taking into account the configuration of the deformities. After placement of a columellar strut, alar grafts (ear cartilage) were sutured to the lateral crura. The tip projection and definition were improved with an onlay graft and a thin septal graft was positioned in the infra columellar area. The patient is seen 1 year postoperatively.

Alar Deformities

Alar deformities and collapse may be caused by overresection of the cephalic portion of weak, concave, long, or malpositioned lateral crura and by resection of the domes, which may lead to medial movement of the lateral crura or by muscular disruptions, particularly disinsertion of the alar base. Resections of significant portions of the lateral crura and postoperative soft tissue contraction can damage the external valvular support and impair the airway. The external valve, which is caudal to the internal valve, is composed of the cutaneous (external and vestibular skin coverings) and skeletal (lateral crura) support of the mobile alar wall. The lateral walls are observed for external abnormalities, such as an inward bowing of the alae on inspiration, with or without alar collapse. One should look for mucosal scars in the form of synechia or bands and deviations of the anterior septal border.

Potential Problems

Alar collapse may occur when the lateral crura are long, weak, and concave. Dome resection and reduction of the height of the lateral crus exacerbate the condition if these factors exist.

Depending on the appearance of the soft tissue cover, the shape, length, and elasticity of the alar cartilages, and the extent of the collapse that is apparent on forced inspiration, the surgeon can reinforce the cartilaginous framework, modify its shape or the shape of the domes, and reinforce the tip supports and the junction between the lateral crura and the upper lateral cartilages. Careful external and endonasal observation of the motion of the ala is crucial, because it will show the affected area and consequently show where to position the graft.

Correction

Exteriorization of the lateral crura by a marginal incision or, preferably, an external transcolumellar approach allows these modifications to be made with accuracy. Lateral crura that are very concave can be corrected by modifying their curvature with light cartilaginous superficial incisions in conjunction with suture technique or thin cartilage grafts. In thin skin, the cephalic portion of the lateral crura can be resected, placed superficially to the concave lateral crura, and sutured to the remaining cartilage with apposition of the concave surfaces.

A thick septal fragment can be spliced into two 0.5 mm thick alar grafts, which is the average thickness of lateral crura. The fragment is placed in a groove 0.5 mm deep. The graft is firmly pressed with the thumb and, with the use of a No. 11 blade, it is meticulously split longitudinally. The procedure works well with septal and costal cartilage, providing slightly convex strips of cartilage. In thick skin and weak, concave cartilages, it is better to use more resistant cartilage, such as a fragment of septal or conchal cartilage that has been modified as necessary.

A wide base of the columella may be caused by a thick septum that needs to be thinned, or lateral edges of the nasal spine that need to be reshaped. The divergent medial crural footplates should be partially resected after the intervening soft tissue is excised and transfixion sutures are placed to ensure narrowing of the columellar base.

An excess of mucosal tissue at the base of the columella can form a bulge. To prevent this, the mucosa can be resected over the septum and the skin covering the columellar base can be advanced, after partial resection of the tail of the medial crura.

After a primary rhinoplasty, this patient had a narrow nose, asymmetry, and collapse of the middle vault (more noticeable on the left side), and a narrow nasal base with exposed nostril orifices. On basal view, the nostril orifices were narrow with a wide columella, and there was internal and external valve dysfunction. On lateral view, there was a round nasal tip, a slight supratip excess, and bilateral alar retraction.

The goal of secondary rhinoplasty was to improve her function by widening the middle vault and nasal base and to correct the alar retraction. A transfixing incision allowed a shortening of membranous septum (2 mm) and caudal septum (4 mm high); the nasal spine was conservatively resected. A transcolumellar incision provided full exposure and allowed major harvesting of septal cartilage and vomer. Cartilage and vomer grafts were placed in the middle vault and nasal base: two spreader grafts in the middle vault, the left one being thicker, and two vomer fragments placed superficially at the junction of the lateral and upper lateral cartilages. A cartilaginous alar graft was then placed on the left side and a vomer graft on the right. A tip graft was placed in the infratip to widen the tip lobule and provide better definition and projection. The patient is seen 13 months postoperatively. Her nose is more harmonious and her ability to breathe has improved.

Short Nose

A short nose is defined as having a decreased distance from the radix to the tip and an obtuse nasolabial angle of greater than 110 degrees with increased show of the nostrils on frontal view. Whether primary or secondary, the foreshortened nose is considered one of the most difficult for rhinoplasty surgeons to treat, particularly when the covering tissues are scarred and adherent and there is a shortage of lining.

Causes

Why is the nose shortened? Assessing the causes of shortening may help to predict the potential lengthening of the mucosal lining and covering soft tissues. A short nose can result from excessive resection of the dorsum, the caudal and membranous septum, the cephalic portion of the lateral crura, and the caudal portions of the upper lateral cartilages. Cephalic rotation of the nasal tip can be caused by a columellar strut or by cephalic displacement of a tip graft, increasing the angle of rotation.

Diagnosis

A diagnosis of nasal foreshortening is based on different methods of measurement. The nasal length depends on the size and proportions of the other facial features and should be proportional to the forehead. Ideally, the nose lies within the middle third of the face. However, in assessing the length of the nose, there are several anatomic deficiencies and disproportions causing real as well as illusory perceptions of shortness. The optical illusion of nasal length is intimately related to the position of the radix and to the nasolabial angle that determines the position of the subnasion.

The position of the nasion is critical; the “ideal position” is a specific point at the deepest portion of the nasofrontal concavity. It is normally situated between the level of the supratarsal fold and the lower eyelashes. Surgical maneuvers can alter the position of the nasion. Grafting the dorsum may shift the position of the nasion upward, creating an illusion of lengthening. An obtuse columellolabial angle greater than 110 degrees with an increased nostril show on the frontal view increases the optical illusion of shortness. Infratip grafts decrease the angle of rotation, shifting the tip-defining points caudally.

Correction

The short nose has always been a difficult challenge. The foreshortened nose is caused by overresection, with retraction of the soft tissue envelope covering the overreduced and unsupported skeleton, thus moving the mobile nose (alar complex) cephalically. The principle of lengthening is to caudally extend the mobile nose. This requires large soft tissue undermining and extramucosal dissection, followed by releasing mucosal incisions and a lengthening of the underlying skeleton. Various procedures, grafting in particular, can be used to produce a real or optical illusion of lengthening. Significant improvement, including optical illusion as well as real lengthening, can be achieved by adequate soft tissue release, alar columellar complex release, and grafting to hold the tip in a more caudal position.

Approach

The transcolumellar approach is best for correction of overshortening of the nose, affording a wide and better access to external soft tissues and facilitating safe mucosal dissection. In correcting a foreshortened nose, there is no risk of overcorrection because of the limiting factors: a most important factor is the suppleness of the soft tissue envelope and the importance of lining contracture. The surgeon can also produce an optical illusion by shifting the radix cephalad, either by deepening a shallow radix or by grafting the dorsum and radix. This can also be done by decreasing a high tip projection and deepening an obtuse nasolabial angle by resection of a protruding nasal spine and caudal septum.

Soft Tissue Release

Wide undermining of the soft tissue cover should extend upward to the radix and widely over the lateral walls if a lateral osteotomy is not planned. The advantage of this undermining is that one is able to use the elasticity of the skin in the hope that it will adapt itself to the newly lengthened infrastructure. Good skin elasticity allows better adaptation of the undermined soft tissues.

In severely foreshortened noses, the undermining can be carried out beneath the nasal bones, the frontonasal apophyses, and the margin of the piriform aperture. Thus the cartilaginous vault is dissected off the bony vault, making it possible to extend the entire cartilaginous nose downward.

Release of the Mucosal Lining

Release of the mucosal lining and laxity of the membranous septum are essential. Dissection of the mucosa is possible when the mucosa is supple and nonscarred and when it has previously been easily dissected. Medially, bilateral mucosal undermining is performed as in an extramucosal dissection, beneath the upper lateral cartilages. This undermining extends up to the level of the piriform aperture.

The lateral crus is separated from the upper lateral cartilage by spreading motions of the scissors, followed by placement of a graft in the gap that has been created. The upper lateral cartilages are separated from the septum and, after traction has been applied to the tip with a hook, staggered and horizontal mucosal releasing incisions are made in the mucoperichondrium of the newly developed mucosal sleeve at the level of the middle third; this allows the lower lateral cartilage complex to be pulled caudally. Mattress sutures are then placed while traction is applied to the alar complex in a caudal direction above the caudal septal border to stabilize the new position of the mucosa. In severe cases, a significant tear of mucosal lining may occur that necessitates a composite conchal graft to fill the void.

Grafting

The osteocartilaginous framework can be lengthened by grafting after the previously described preliminary but crucial maneuvers are performed, producing a real and/or optical illusion of lengthening. Dorsal grafts allow correction of saddle deformity and provide an illusory lengthening by shifting the nasofrontal depression upward. A long dorsal graft (as a bone or costal graft) extending to the tip can provide real lengthening by a forceful downward pull of the alar lobular complex, moving the tip and defining points caudally.

Caudal extension grafts can also be used. A long, rigid batten septal extension graft can be sutured along the lateral edge of the septum. This graft should be 3 cm long, its stiffer portion protruding caudally by 6 to 10 mm.

This patient was very depressed after a rhinoplasty that resulted in overshortening of her nose; the nostril orifices could be seen on frontal view, and the nasal base was flat and widened. Her principal request was correction of the shortening as well as widening of the nasal base, yet she wanted her dorsal hump preserved. On lateral view, she had a slight dorsal hump and a round tip without definition. The nasolabial angle was increased, and the facets were too visible on both sides. On basal view, one could note the signs of the loss of tip support: a short columellar distance, widening of the medial crural footplates, and alar flaring with soft tissue facet ptosis resulting from a loss of support that was more noticeable on the right.

Because the patient wanted to preserve her dorsal hump, the objectives were to provide some lengthening, improve the tip supports, narrow the nasal base, and give the tip more definition. A transfixion incision was first done to decrease the nasolabial angle with a triangular, posteriorly based resection of caudal septum, mucosa, and nasal spine. The incisions were sutured and a transcolumellar incision was made; after a dorsal approach to the septum and a large extramucosal dissection, this allowed major en bloc septal harvesting and releasing mucosal incisions at the level of the rhinion. A long, thick fragment from the caudal portion of the harvested material was found particularly appropriate for use as a septal extension graft. The thicker end of this fragment was split and placed as a tongue-in-groove at the caudal border of the septum and was fixed with 5-0 PDS sutures. Lateral elongation was obtained by spreading the lateral crura from the upper lateral cartilage using scissors. The alar complex was then extended caudally with a double hook, and a needle was placed to maintain the lengthening while transcolumellar sutures were performed with 5-0 PDS.

A shield graft was positioned in the infratip segment, and a septal graft was spliced, bruised, and placed caudally to the anterior base of the main graft to provide a smooth transition from the main tip graft to the adjacent facet.

The patient is shown 8 months postoperatively. Her nose appears longer and its contours are aesthetically pleasing.

One can also use a triangular caudal extension graft based anteriorly (8 to 10 mm) and positioned within the membranous septum; its fixation to the caudal septum can be achieved with figure-of-eight sutures, transmucosal mattress sutures, and external splints. An excellent fixation can be achieved by securely splinting (sandwiching) the graft with two PDS battens.

Two PDS battens are sutured laterally to the caudal septum and then to the graft. Because PDS resorbs in 6 months, it provides a scaffold for a good stabilization by the fibrous tissue produced during the healing period.

Cartilage grafts to the tip may provide a lengthening effect by using multilayered grafts placed caudally to the infratip lobule. These grafts must be thicker anteriorly and feathered out posteriorly so as to decrease the angle of rotation. They can also improve contour and projection if necessary. Infratip grafts allow the surgeon to shift the tip defining points caudally and to provide a real lengthening. The recipient graft bed should be strong enough to resist the cephalic pull of the stretched skin flap. This is achieved by the caudal extension graft placed within the membranous septum and columella.

After having undergone two rhinoplasties and septoplasty, this patient complained of an overshortened nose with exposed nostril orifices and difficulty in breathing. On lateral view, the dorsum was straight, but there was an overtight rotation, and overshortening of the tip with an increased columellolabial angle at 130 degrees. There was some a prominence on the right ala and a slight depression of the left nasal bone and middle vault. Her soft tissues were quite thick.

On frontal view, the patient's overexposed nostrils are evident, and her upper lip appears too long. Rhinoscopy revealed a septal deviation on the left side, and on palpation of the septal mucosa with a soft instrument, it appeared that the septum had been partially harvested previously. The goal was to decrease the angle of rotation and correct the deformities. Because no septal cartilage was left after the previous septorhinoplasties, the right concha was harvested using a retroauricular approach. A transcolumellar approach was selected; a posteriorly based triangular resection of the caudal septum, nasal spine, and mucosa was performed through a posterior transfixing incision.

After skeletonization, direct visualization showed overresection of posterior portion of lateral crus and a slight prominence of the left dome. Dissection of mucosal flaps permitted to correct the septal deviation and harvest a small portion of septal cartilage. The domes were equalized by resection of the left dome. An alar graft was sutured to the remaining portion of the right lateral crus. A lateral low-to-low osteotomy was performed on the left side. A spreader graft was placed on the left side and diced cartilage fragments were placed laterally to the upper lateral cartilage–nasal bone junction to correct a depression. A triangular caudal extension graft based anteriorly was positioned in the membranous septum and stabilized with two PDS battens. A two-layered infratip graft was positioned and sutured, and a buttress graft was positioned cephalad to the anterior portion of the graft and sutured to the domes. A 2 mm alar base resection was then performed. The patient is seen 16 months postoperatively.

An obtuse nasolabial angle with overexposure of the medial crura footplates may be decreased by a resection of nasal spine and a triangular based resection of caudal septum and mucosa. A composite graft harvested from the concha is indicated if the gap between lower and upper lateral cartilage is large. The purpose of this graft is to fill the void. The dressing is positioned while the nose is maintained in extension with a double hook instrument.

Correction of a Short Nose

The short nose has always been a difficult challenge. Correction should resort to optical illusion effects as well as true lengthening effects. Before grafting, three crucial points should be considered:

- Undermine a large soft tissue cover.
- Perform a release of the alar columellar complex and mucosa.
- Graft so that the tip is in a more caudal position.

Retracted Columella

Columellar retractions may be observed after an excessive resection of the antero-caudal septum, the nasal spine, or the membranous septum. The columellar retraction can be located at the midcolumella or at the labiocolumellar junction, with an acute nasolabial angle as a result of septal or nasal spine overresection.

Gunter thoroughly described the alar-columellar relationship. On lateral view, the outline of the nostril is an oval, which should be separated in two equal segments by its long axis. The relationship of the columella to the long axis defines the retracted columella. It can be combined with a hanging ala, decreasing the columellar show.

Palpation with columellar mobilization allows evaluation of the nasal tip supports and the suppleness or rigidity of the membranous septum. Anterior rhinoscopy with palpation of the lining with a blunt instrument establishes the location of a septal deviation, the location and extent of a caudal septal resection, and whether septal material is available for grafting.

The open approach and transection of the upper lateral cartilage–septal junction after an extramucosal dissection allows a perfect exposure of the septum and facilitates assessment of the deformities or defects. Septal deviations are always corrected before any further correction is performed.

Correction of the retracted columella must be graduated, taking into account the retraction extent, the suppleness or laxity of the lining, the tip, and the position of the alae. Tip support has often been weakened and must be reinforced with sutures and grafts.

Moderate Columellar Retraction With Supple Lining

A columellar strut is sufficient for the correction. It is preferentially harvested from the septum, rectangle, measuring 15 to 20 mm long and 3 to 5 mm wide. It is placed between the middle and intermediate crus, slightly extending in the membranous septum. It is sutured with two or three 5-0 PDS stitches.

A columellar onlay graft extended toward the nasal spine may sometimes improve the columellar show.

An acute labiocolumellar angle caused by excessive trimming of the caudal septum, of the nasal spine and sometimes of the membranous septum can be corrected with a posterior-base triangular columellar strut. It leans against the nasal spine and extends into the membranous septum. Small pieces of cartilage can be added in the premaxillary region to lower the labiocolumellar junction.

Significant Columellar Retraction With Scarred Lining

When the alar-columellar distance is less than 1 mm, lengthening of the caudal septum must be combined with lengthening of the lining.

Lining Lengthening

If possible, wide extramucosal bilateral undermining is first performed. Then staggered horizontal incisions of the lining are made in the middle third. Transfixion stitches are placed at the caudal edge of the septum while the lining is pulled inferiorly with hooks to keep the lining in a downward position.

When the scarred tissues cannot be undermined, a bilateral V-Y plasty can be done during lining closure. If not possible, composite chondrocutaneous grafts can be used. They are sutured in two hemitransfixion staggered incisions in the membranous septum.

Caudal Septum Reconstruction

Columellar retraction is corrected by placing a graft that extends the missing caudal septum (septal extension grafts). This graft must be aligned with the straightened septum. If possible, it is harvested if possible en bloc at the posterior part of the septum, preserving at least 8 to 10 mm above and in front of the defect. A stiff, flat piece of cartilage is preferentially obtained at the posteroinferior part of the harvested graft, at the junction between the septum and vomer.

If the septum is not available for the septal extension grafts, the graft material can be harvested from the conchae. It can become straighter and stiffer by suturing two pieces of conchae with the concavities facing each other. A graft can also be harvested from the rib, especially if cartilage must also be used for dorsal augmentation or for other grafts. It is then taken in the central part of the rib and sutured after waiting at least half an hour to be certain that no late bending will occur.

Different types of septal extension graft designs exist. The triangular caudal extension graft is stabilized with PDS battens (0.25 mm thickness). Fixation of the graft to the nasal spine is made with 5-0 PDS after having placed the inferior edge of the graft in a groove made behind the nasal spine. If the spine has previously been resected, two converging drill holes are made in a V shape in the premaxilla to allow a strong fixation of the graft. Fixation of the graft between the middle crura is done only after having first temporarily closed the transcolumellar incision and assessed its impact on the columella position.

Finally, an infracolumellar graft can be added before closure if more lengthening is needed or if the columellar contour must be softened. Transfixion resorbable stitches are made through the septum and graft to prevent dead space. An endonasal splint and packing help to prevent fluid accumulation between the lining.

This patient underwent two rhinoplasties; the dorsum and caudal septum were over-resected. On lateral view, a light fullness of the radix could be seen, with saddling in the upper dorsum and a supratip convexity. The columella was retracted, particularly in its middle portion, highlighting the crooked aspect of the tip. Both alae were markedly concave and collapsed.

On frontal view, the dorsum was flat, with a rather narrow middle vault and a pinched tip lobule. On basal view, the infratip segment was concave and the columella appeared short. The objectives were threefold: correction of the retracted columella, the depressed dorsum, and the collapsed alae. After harvesting the conchae through a retroauricular approach, a transcolumellar approach was performed; dissection was tedious in the alar region because of adherent soft tissues. Operative findings showed some rests of the right lateral crus and a concave lateral crus on the left side. The radix was slightly reduced with a beveled osteotome.

The septum was approached via its dorsal edge and an extramucosal dissection was performed, allowing a large septal harvesting and conservative resection of nasal spine. Two horizontal staggered incisions were made in the midportion of the dorsum to provide some lengthening of the mucosal flaps. Mucosal lengthening was held in caudal extension with two hooks, and sutures were placed a few millimeters above the caudal border of the septum to stabilize the mucosal lengthening. Lateral low-to-high and medial osteotomies were performed. A 5 mm wide columellar strut was positioned between the caudal septum and the cephalic edges of the medial crura. It was sutured to the nasal spine and to the caudal septum. The rests of the right lateral crus were removed, and alar reconstruction was achieved with a conchal graft sutured to the dome. The left concave lateral crus was corrected by suture technique. Additional grafts were placed, caudally to the columella to provide additional exposure of the columella, and in the infratip region to correct the depression in this area. A two-layered dorsal septal graft was then placed on the dorsum. The patient is seen 12 months postoperatively.

Nasal Tip Deformities: Problems Associated With Soft Tissue Conditions

Secondary defects of the nasal tip are the most difficult to correct. The patient should be advised that revisions are increasingly difficult and the outcome even more unpredictable.

Secondary deformities of the nasal tip are often caused by excessive and asymmetrical resection of the alar cartilages, notably in the lateral portions and at the level of the middle crura. Depending on the skin condition, overresection can cause various types of defects, but thick skin provides some support to the alar cartilages and can also mask a projection or a cartilaginous defect. A wide range of deformities may be seen in the nasal tip area. The most common nasal tip defects include the following:

- Minor defects such as a slight asymmetry of the domes and lateral crura despite perfect correction via an open approach and perfect symmetry at the end of the procedure

- Malposition of the domes' height and projection, nasal tip deviation, and a tip lobule that is too narrow or broad

- Undercorrection that leaves an excess of tip projection, a wide lobule, tip ptosis, and cartilaginous projections

- Undertip projection of variable severity—from inadequate tip projection with a round nasal tip, frequently observed after a loss of tip support, to a major undertip projection caused by aggressive resection of the domes and lateral crura

- Overrotation of the tip, with an increased angle of rotation

Overresection of the vestibular skin and mucosa can result in alar retraction that exposes the columella. Secondary problems may be worsened by scarred soft tissues that are very adherent to the underlying structures, making dissection very difficult. Collapse and depression of the nasal ala are often associated with overresection of the lateral crus: it weakens the cartilaginous support of the ala, creates alar notching or retraction, and may impede the external nasal valve.

Correction

Deformities of the nasal base should be corrected taking into account the aesthetics and the defects that are noted in other structures of the nasal pyramid, notably the radix and dorsum, to reestablish an equilibrium between the subunits of the nasal pyramid and to balance nasal harmony.

A transcolumellar approach is most often required to assess the deformities and the remaining cartilages. This approach allows a larger array of suture corrections, better positioning and accurate suture fixation of the grafts, and more accurate positioning of camouflage methods.

When after several surgeries soft tissues have become very scarred, a midcolumellar incision can be used for easy placement of a tip graft.

This young postrhinoplasty patient complained of an unbalanced nose: a wide nasal base, slight saddling of the dorsum, and bilateral alar retraction. On lateral view, the upper dorsum was too low and the alar retraction was very marked on the anterior portion of the alar rim.

The basal view showed an asymmetry of the nostril orifices. Soft tissues were moderately thick and tip support was poor. On frontal view, there was a narrow bony vault and a large, wide nasal base, with some irregularities on the surface of the tip lobule; in addition, the nostril orifices were too exposed. These deformities were obvious on oblique view, showing the flatness of the infratip. The objectives were to balance the nose on lateral and frontal views, improve the tip configuration, definition, and width, and correct the alar retraction. After harvesting auricular cartilage from the concha, a transcolumellar approach was selected. Dissection was difficult

because of a scarred supratip; defects were observed, particularly on the overresected lateral crura, which were reduced to some unusable fragments of cartilage for correct reconstruction and these were resected.

After rasping some irregularities of the dorsum, the supratip excess of septal cartilage was incrementally shaved, and a septal approach allowed for a major harvesting. Reconstruction had started by strengthening the columella support with a septal columella strut. A multilayered dorsal graft was composed of a long fragment of septal cartilage, a bruised fragment of the resected lateral crura placed superficial to the main graft on its cephalic portion, and a bruised auricular cartilage placed underneath to augment the radix area. Alar reconstruction was achieved with two septal battens positioned parallel to the alar rim and sutured to the vestibular skin. A tip shield graft of ear cartilage was placed in the infratip lobule, and two buttress grafts were positioned posterior to its anterior portion to decrease a large angle of rotation. No osteotomies were performed. Results are shown 2 years postoperatively.

Scar Tissues

Difficulties are encountered when soft tissues are very scarred, and dissection should be performed very careful to avoid dermal damage or skin perforation. This scar tissue will sometimes be left on purpose. It can be sculpted to get a better tip and supratip definition. It may also provide a solid foundation for graft placement and fixation. A thin layer of scarred soft tissue can be left at the surface of the alar cartilages to facilitate suture techniques.

Excess width and tip projection can be controlled with a bloc sagittal wedge resection of scar tissue in the dome area, followed by approximation of the edges with sutures.

An approach to the septum can be facilitated by sagittally splitting the section of scarred tissue with a blade, starting from the inferomedial crura space up to the tip and supratip.

Thinned Skin and Subcutaneous Tissues

From prior rhinoplasties, the superficial nasalis aponeurotic system (SMAS) and skin may have been traumatized and may become thinner and more adherent to the underlying structures. In those cases, sutures are favored to graft techniques whenever they are usable. However, a camouflaging maneuver can be useful to hide small cartilaginous irregularities or the graft edges. Usually a sheath of deep temporal aponeurosis is sutured on the top of the tip or the tip graft. Perichondrium can also be used for this purpose.

Reconstruction

Reconstruction involves strengthening of the tip supports. After having harvested cartilage from the septum or other sites, the surgeon should, as in every rhinoplasty, establish a solid, stable, symmetrical foundation and strengthen the medial leg of the tripod. It is also essential to obtain a straight septum to correct any extrinsic tip asymmetry.

The dome height, position, and symmetry can be corrected only after a stable foundation has been established. If cartilage conditions are good, suture techniques may be used to improve symmetry and projection and to narrow a broad tip lobule. Sutures can also enhance tip definition if the skin is not too thick.

If the columellar graft is too malleable (ear or soft cartilage), its rigidity can be improved by assembling two grafts or sandwiching them with a thin fragment of vomer or a PDS plate. When the columella is retracted, the columellar strut is positioned within the membranous septum and medial crura. It should be wider than usual struts to allow a caudal shift of the medial crura. When alar cartilages are too soft or are unusable, it is sometimes better to resect and reconstruct them with cartilaginous graft.

Tip asymmetry after a correct septal alignment sometimes requires asymmetrical resection of the domes or middle crura. An interdomal suture is then placed to equalize the dome's height.

Various types of tip grafts are used to reconstruct the nasal tip and improve its contour, projection, position, and the alar-columellar relationship. The surgeon can use onlay, shield, or buttress grafts. These grafts are often used in combination.

A tip graft should always be placed on a well-prepared, symmetrical recipient graft bed. This can be created by judicious resection of the cartilaginous graft bed. The caudal edges of the middle crura are equalized to provide a flat, symmetrical graft bed, or an asymmetrical graft is placed (*left*). When it is difficult to obtain a flat, symmetrical recipient graft bed, a small graft can be positioned on one side, above the lateral portion of the shield graft, to compensate and correct an asymmetrical recipient graft bed.

This patient had severe deformities and impaired breathing after a septorhinoplasty. On lateral view, there was saddling of the upper dorsum and radix and a marked supratip convexity. The columella was retracted in its posterior portion. The soft tissue cover was thin, highlighting the deformities and projection of the cartilages.

On frontal view, the bony vault was slightly broad in proportion to the width of the middle vault and the collapsed alae. The nasal base was very asymmetrical, with significant alar collapse on the left side. The tip and columella were deviated toward the right. Cartilage was harvested from both conchae, and correction was achieved with a transcolumellar approach and careful skeletonization in a subperichondrial and subperiosteal approach to preserve sufficient thickness to the covering soft tissues as much as possible. The deformities observed on direct view were marked, with asymmetry of the resections and scar tissue in the supratip. A large posterior portion of the right lateral crus had been resected, and the left lateral crus was very concave and thin. Scarred supratip soft tissues were trimmed, as well as 3 mm of the supratip dorsal edge.

Despite a previous septal surgery with its consequent scarred mucosa, harvesting of the posterior septum was possible. Reconstruction was achieved with a spreader graft on the left side and an autospreader graft with internal plicature of the dorsal edge of the right upper lateral cartilage. After resection of the rests of the domes and the left lateral crus, which was not usable, alar grafts (ear cartilage) were positioned on the alae. Multilayered grafts composed of two septal fragments were placed on

the upper dorsum, and two fragments of the resected lateral crus were placed superficial to the main dorsal graft in the radix area. Results are shown 2 years postoperatively.

This 23-year-old patient had undergone two prior rhinoplasties. On the lateral view, the nose was short and unbalanced, with a low upper dorsum, a high cartilaginous dorsum, a round tip with no definition, and an increased angle of rotation. The frontal and oblique views further demonstrated the bulbosity of the nasal tip and low upper dorsum. On palpation, the soft tissues of the tip lobule were thick and lacked suppleness.

A triangular posteriorly based resection of mucosa and caudal septum was performed using a transfixion incision. After a transcolumellar approach and skeletonization, the fibrous, scarred soft tissue of the supratip was resected and the dorsal border trimmed by 2 mm. Operative findings showed the previously resected domes and a slight tip deviation on the right side. A major harvesting of septal cartilage was then performed using the hemitransfixion incision.

A two-layered, bruised cartilage was placed on the upper dorsum. The cut ends of the previously resected domes were sutured after some adjustments. A columellar strut was then placed within the medial crura and fixated with 5-0 PDS. A double-layered shield graft was then placed in the infratip to augment tip projection and the length of the nose. The patient is shown 18 months postoperatively.

In major undertip projection, multilayered grafts can be used. A long and stiff columellar strut resting on or fixed to the nasal spine can be covered by multilayered onlay grafts. All of these grafts (septal or ear cartilage) are accurately positioned and sutured with 6-0 PDS.

Buttress Graft

A long infratip shield graft projecting several millimeters above the domes can also be used. However, the anterior extension of the tip graft should be buttressed with a graft placed cephalad to the main graft and sutured to the anterior septal border or to the domes to prevent the anterior portion of the graft from being folded cephalically by an inelastic or rigid soft tissue cover.

When alar flaring is associated with an undertip projection, it should be corrected only after nasal tip reconstruction. Any residual flaring can be assessed and then corrected.

Problems Associated With Soft Tissue Conditions

At the end of a rhinoplasty procedure, the result may appear satisfying. The dressing often consists of adhesive tapes that put some pressure on the supratip. There will be residual supratip fullness caused by edema, which can persist for several weeks and will require massage or prudent injections of corticosteroids. After a few months, one can assess the nose for a definitive polly-beak deformity.

Polly-Beak Deformity

Polly-beak deformity, one of the most obvious signs of a previous nasal operation, is characterized by a supratip convexity that appears more pronounced when it is associated with a lowered dorsum and underprojection of the nasal tip. It may result from a technical mistake or a lack of appreciation of the dynamics between skin cover and the underlying skeleton, with inability of the soft tissue cover to redrape properly over the new skeletal structures.

Causes of Polly-Beak Deformity

CARTILAGINOUS UNDERRESECTION Cartilaginous polly-beak deformity is more frequently caused by a lack of sufficient septal resection (anterior angle) than to insufficient lateral crus resection (cephalic border at the dome junction). At the end of the procedure, it is common to underevaluate the levels of difference between the domes and the dorsal border of the septum in the supratip area; 5 to 6 mm is appropriate in thin skin and up to 10 mm in thick skin. Any cartilaginous excess must be resected if the nasal tip support and projection are appropriate and if skin elasticity is good. Otherwise, more tip projection must be obtained, either through sutures (septocolumellar sutures are the most useful for this purpose) or through the use of a long columellar strut on which the medial crura are shifted anteriorly, or a tip graft.

CARTILAGINOUS OVERRESECTION Excessive resection can lead to the same deformity as underresection, although by different mechanisms. Two main preoperative factors favor a cutaneous polly-beak deformity:

Thick and loose covering tissues that will not retract in the supratip area.

Preexisting tip with inadequate projection: incisions and resection will increase the lack of tip projection. If not corrected, this lack of projection creates bulk in the supratip area.

The common operative factor is a large resection of the cartilaginous hump with loss of nasal tip support. This excessive hump removal occurs more frequently when the radix is low and is not corrected. Poor redraping of the soft tissues over the osteocartilaginous skeleton remains the primary cause; in a patient with thick skin and poor skin elasticity, the surgeon should not hope that the skin will redrape to the new skeletal structures. Polly-beak deformity is often associated with a lack of definition of the tip lobule or a round tip.

Surgical Correction

It is easy to use morphing software to preview a pleasing nose for the patient, but what really matters is that the patient leave the operating room with a satisfying long-term result. This is achieved by establishing an adequate underlying skeleton with good tip support, taking into account the dynamic balance that should exist between soft tissue cover and the underlying skeleton.

In thin, elastic skin, excesses of the anterior dorsal border of the septum, upper lateral cartilage, and cephalic edge of the lateral crura can be easily trimmed. In the nasal tip, a single or multilayered onlay graft or a rigid infratip graft will provide better projection and definition.

In thick skin, a conservative surgery should be performed with dorsal and nasal tip augmentation that would make the supratip excess disappear. The tip supports should be strengthened, and tip projection should be augmented. If a tip graft is positioned in the infratip, it should pass 3 to 4 mm beyond the level of the domes and be adequately buttressed to prevent folding of the graft under pressure from a rigid soft tissue envelope.

The supratip subcutaneous tissues can sometimes be gently trimmed with scissors. Caution is paramount, and preferably this resection is done without turning over the supratip skin. Any dead space in the supratip area should be eliminated by approximation of the dermis to the underlying septum.

This 20-year-old patient had undergone two previous rhinoplasties and septoplasty. His main request was to have a thin, narrow tip lobule. On lateral view, there was supratip fullness with a round nasal tip and a slightly depressed upper dorsum, as clearly seen on the oblique view.

The frontal and basal views showed a broad tip lobule with no definition and the alae looked flared. On palpation, the soft tissue cover was thick and difficult to pinch, precluding any tip reduction. The objectives were to augment the upper dorsum and to give the tip more definition.

After skeletonization through an open approach, the supratip dorsal excess was trimmed. The radix was slightly deepened with an osteotome, and the upper dorsum was rasped for removal of soft tissues and placement of a dorsal graft. A large septal harvesting was performed through a hemitransfixion incision, and the grafts were positioned. On the upper dorsum, a two-layered graft composed of one piece of cartilage and vomer was placed. An additional graft was placed superficially.

A columellar strut (fragment of vomer) was placed within the medial crura, and the tip was grafted with a rigid infratip graft extending 5 to 6 mm above the domes. The pressure of the soft tissue cover was pushing the tip graft cephalically. A buttress graft was placed above the tip graft and was sutured to the dorsal septal edge to prevent cephalic displacement and provide the graft with strong anterior projection. Because of the soft tissue thickness, there was no risk that the graft would be visible. A 3 mm alar base resection was performed. The patient is seen 2 years postoperatively.

In a large nose with thick skin, sometimes the only alternative is a vertical fusiform resection in the supratip area. This provides the tip with better definition, but at the price of a scar. Would the patient prefer a scar that is often not noticeable to a supratip convexity with lack of harmony? The decision lies with the patient.

After having undergone two previous rhinoplasties, this patient presented with a long nose and a polly-beak deformity, as seen on the lateral view. On the frontal view, the tip was bulbous with no definition.

Sequelae of radiation therapy prescribed by a previous surgeon for correction of the polly-beak deformity were observed in the supratip area. On palpation, there was significant laxity of the tip and supratip soft tissue cover. Because this patient was tall and had a long, large nose, a reduction rhinoplasty was contraindicated, so a skin resection was planned to reduce the supratip skin excess. This patient was a participant in this decision, taking into consideration the poor quality of the skin surface and a horizontal scar at the superior limit of the supratip.

After a horizontal, full-thickness resection of the supratip soft tissue cover and skeletonization, the hump was resected with an osteotome. Septal cartilage was then harvested through a hemitransfixion incision, and an onlay tip graft was positioned

through the supratip opening. After lateral osteotomies and alar base resections, subdermal and running sutures were carefully placed. The patient is shown 32 months postoperatively; the horizontal scar is scarcely visible.

In a patient with loose skin without elasticity that can be easily pinched because the subcutaneous layers are very loose, correction also includes a nasal tip augmentation and, when possible, dorsal augmentation with cartilage grafts.

Polly-Beak Correction

Assessment

- Soft tissue thickness and scarring
- Tip supports
- Septal alignment
- Tip asymmetry

Reconstruction

- Septal alignment and harvesting
- Strengthening of tip supports
- Providing balance with other subunits
- Ensuring tip symmetry with resections, suture techniques, and grafts
- Use of tip grafts for contour, projection
- Use of alar grafts

Complications

The term *secondary rhinoplasty* in this chapter is taken to mean surgery on a post-surgical nose. This frequently includes patients who have undergone three, four, or more extensive operations on their noses. As the catalog of previous procedures lengthens, the proportion of cicatrix in the nose increases, and the flexibility of the tissues diminishes for further reshaping. It is not easy to separate unfavorable results and complications, because they overlap to a certain extent, a complication being considered an unexpected sequela.

A *surgical complication* means a mishap that occurs during the operative or healing phase of surgery that could possibly have been avoided by the surgeon. In secondary rhinoplasty, however, it describes any unfavorable outcome. Failure to meet the goals set out before surgery is almost always interpreted by the patient as a complication, despite a repeated and meticulous process of informed consent. Allied with the unfavorable anatomic and psychological terrain, the inevitable postoperative

scrutiny that accompanies secondary rhinoplasty makes it inherently prone to functional and aesthetic complications. The most common complication is postoperative bleeding. Infection usually responds well to antibiotic therapy. Severe complications during and after rhinoplasty are rare. Some are anecdotal.

Hemorrhage

Excessive bleeding may occur during or after surgery and is said to occur more commonly when associated septal or turbinate work has been done. Overall, it occurs in approximately 2% to 3% of rhinoplasties. Intraoperative bleeding may become problematic during inferior turbinectomy unless excision of the bone is carried medially at its posterior end to avoid the vascular pedicle that arises from the lateral nasal artery. This, and septal bleeding, usually respond to anterior nasal packing if the source of bleeding cannot be identified; the use of pressure balloons, posterior packs, and, very rarely, vessel ligation may become necessary. Postoperative hemorrhage usually stems from anterior septal ulcerations, which are cauterized with silver nitrate sticks in a setting with good lighting and suction available.

The removal of packs in itself may unveil septal ulcerations and cause bleeding, thus throwing into question the need for routine packing in the nose. The use of a headlight and absorbable transeptal sutures after septal harvest (septoplasty), with splints as necessary, obviates the need for bulky, uncomfortable intranasal dressings, which are a source of sinusitis as well as bleeding.

Infection

Infection after rhinoplasty is rare, as would be expected of clean elective surgery in such a richly vascularized territory. Routine administration of antibiotics is not advised, but some surgeons feel more comfortable giving them if grafts have been used. Although rarely indicated in secondary rhinoplasty, any alloplastic material would justify preoperative antibiotic cover with a single intravenous dose. The most common organisms are staphylococci, especially *Staphylococcus aureus*. When infection does occur, the consequences can be serious. There may be an extremely bothersome, localized graft infection that necessitates removal of the graft. Rarely, infection can spread to become severe cellulitis, sinusitis, or even intracranial sepsis. Nasal packing and splintage incurs a small (16.5 per 100,000) risk of toxic shock syndrome in susceptible patients, with a mortality risk of 5% to 10%. Although one may culture nasal flora preoperatively for TSST-1, the staphylococcal toxin responsible, these statistics further underscore the argument for avoiding the use of foreign material in the nose if at all possible.

Localized infections respond to routine measures, such as using targeted antibiotics and direct incision and drainage. Systemic signs of hypotension, rash, and pyrexia with late desquamation signify toxic shock and should be treated aggressively. Menin-

gitic symptoms occurring shortly after rhinoplasty should also be linked to the surgery until proved otherwise, and prompt medical attention must be sought from a medical team.

Columellar Scarring

Secondary rhinoplasty may present an opportunity to revise an unfavorable transcolumellar scar. Any one of the numerous patterns for this incision (chevron, stairstep, curved) may become thickened, hyperpigmented, or, most commonly, depressed, with a visible shadow that interrupts the smooth lines of the columellar pillars.

Depressed horizontal scars can usually be excised at the beginning of the secondary rhinoplasty, with the contours restored by bringing the healthy skin borders together at the end of the operation. Eversion of the columellar skin with carefully placed mattress (6-0 nylon) sutures affords a certain degree of protection from future indentation.

Occasionally fullness is seen at the angles of the scar as it turns into the vestibular incision. This causes the columellar flap to resemble a pincushion, which is evident on the oblique view. When the elevated corner is resutured, it should be delicately thinned of scar tissue with curved Iris scissors and inset under mild tension to flatten the columellar flap over the outer aspect of the medial crus.

Vestibular Scarring

Because nature abhors empty spaces, fresh scars in a multioperated nose are prone to contraction across the vestibule. Webs distort the normal relationship between vestibular skin and nasal mucosa, creating stenosis and synechia. There is usually little choice other than to use standard approaches when reoperating in these cases, releasing any contractures as they are encountered. Some of the more obstructive bands of scar may be resected and resurfaced using adjacent skin or mucoperichondrium, but in the apex of the dome this becomes difficult. Wide release of scar tissue and reapposition of the nasal lining using peanut packs sutured together and placed high against the undersurface of the domes is a useful maneuver in such cases. In refractory cases, perforated nasal splints made of silicone that fill and shape the vestibule are custom made and fitted for as long as the patient will tolerate them.

Severe vestibular scarring in the mucosal lining warrants the use of buccal mucosal grafts, taken from the midlateral cheek and secured with Vicryl sutures. Petrolatum gauze impregnated with antibiotic ointment is necessary for 5 days. Rarely, hinged septal mucoperichondrial flaps based anteriorly on the anterior septal branch of the superior labial artery may be required to resurface a severely scarred dome (Burget), with care taken not to draw the mucocutaneous junction too far caudally below the leading edge of the septum.

Septal Perforation

Septal perforation is a late complication characterized by a complete breach across the septum and its mucosa in the same place. Unless such a tear is meticulously repaired under direct vision and without tension, sometimes with the help of septal splints (using x-ray film or a similar material), a small perforation will result. This may crust and bleed, and whistle during inspiration. It may then be enlarged, repaired using advancement flaps and cartilage grafts, or closed using a septal button if all else fails. Superinfection compounds the problem of trauma.

Traumatic Complications

Traumatic complications result from trauma to the nose itself and adjacent areas, namely, the orbital region, where significant but rare complications may be observed. By the nature of its scarred planes and altered anatomy, the secondary nose is necessarily prone to inadvertent tearing of the SNAS and skin during undermining. Thickening the soft tissue envelope immediately before its dissection by injecting saline solution or a local anesthetic percutaneously can reduce the risk of tearing. Scarring after buttonholing is made more conspicuous if it becomes adherent to the underlying structural framework. It is essential to anticipate this scarring by repairing the SNAS layer if it is identifiable, and by everting the cutaneous sutures.

Osteotomies can damage the lacrimal sac. Intracranial injury and blindness have been described, caused by direct mechanical trauma to the frontal lobe or the optic nerve. Fracture through the cribriform plate may occur after aggressive manipulations with twisting motions on the perpendicular ethmoid plate during a septoplasty.

Concluding Thoughts

The outcome in revision and secondary rhinoplasty depends on many factors, including difficulties of correction that cannot always be predicted. These difficulties may not reflect the severity of the defects. Thus a severe defect may be easier to correct than a very minor one when there is no shortage of graft material and soft tissues conditions are favorable.

Because the nose is positioned in the center and midline of the face, minor defects or asymmetry always bother a more observant and demanding patient. The difficulty frequently lies in convincing a patient who has had a significant improvement with prior surgery to avoid any revision for very minor defects.

If most defects are caused by overbalanced and unbalanced resections and unrecognized anatomic variants, some well-performed rhinoplasties with no apparent defects may still be found to lack harmony and finesse.

In past decades, the open approach and cartilage grafting have been used more frequently. Thus a new set of deformities is emerging, with scarred soft tissues making the external approach more difficult, if not impossible, along with frequent shortages of graft material.

Before undertaking a primary and, a fortiori, a secondary rhinoplasty, the surgeon must ask two questions: (1) Am I able to improve the appearance and/or function of the patient's nose? and (2) Will the patient be satisfied?

Clinical Caveats

The patient and surgeon should make the journey as a team, and any problems encountered along the way are best dealt with as a team.

Secondary rhinoplasty defects require an accurate preoperative analysis of the deformities and assessment of the functional problems.

An aesthetic sense and good knowledge of dynamics and skeletal support are essential to achieve the goals of secondary rhinoplasty.

The open approach provides excellent visualization of the deformities and facilitates graft placement and fixation.

A large skin sleeve cannot redrape over the reduced skeleton.

Because grafting is frequently performed for correction of secondary rhinoplasty defects, harvesting and preparation of grafts are of crucial importance.

Annotated Bibliography

Aiach G, Gerbault O, Gomulinski L, eds. *Rhinoplastie: Voie d'Abord Externe*, 3rd ed. Paris: Elsevier Masson, 2008.

This book is a comprehensive textbook on the primary and secondary rhinoplasties performed through an open approach with its specific philosophy and strategy. A chapter is dedicated to the secondary rhinoplasties, the preoperative analysis, the up-to-date corrections with an emphasis on the grafts and the sutures.

- Constantian MB. Rhinoplasty: Craft & Magic. St Louis: Quality Medical Publishing, 2009.
Much of the second volume of this two-book set is dedicated to secondary rhinoplasties. Unlike the majority of plastic surgeons, Mark Constantian advocates a closed endonasal approach for all cases, with strategic choices completely different from those used for the open approach. The impressive results prove that different ways can be used to achieve good results in secondary rhinoplasty and that mastering both approaches and their specific strategies is important when performing secondary rhinoplasties.
- Gruber RP, Aiach G. Open rhinoplasty. In Goldwin R, Cohen MN, eds. Unfavorable Results in Plastic Surgery: Avoidance and Treatment, 3rd ed. Philadelphia: Lippincott, Williams & Wilkins, 2001.
This chapter considers the complications of rhinoplasty, with an emphasis on those related to the open technique.
- Guyuron B. Secondary rhinoplasty. In Guyuron B, ed. Plastic Surgery—Indications, Operations, and Outcomes. St Louis: Mosby-Year Book, 2000.
A concise yet in-depth review of postrhinoplasty defects and their correction using innovative techniques.
- Rohrich RJ, Sheen JP, Teotia SS. Secondary rhinoplasty. In Grotting JC, ed. Reoperative Aesthetic & Reconstructive Plastic Surgery, 2nd ed. St Louis: Quality Medical Publishing, 2007.
This book covers many problems commonly found in secondary rhinoplasty and nasal reconstruction, presenting both endonasal and open approaches to reoperative rhinoplasty.

CHAPTER 58

Ethnic Rhinoplasty

WILLIAM D. LOSQUADRO, DEAN M. TORIUMI

The term *ethnic* can be applied to a group of people who share a common racial, cultural, national, religious, or linguistic heritage. It is commonly used in the United States to describe nonwhite minority groups. According to the American Society of Plastic Surgeons, cosmetic procedures for ethnic patients increased 11% in 2008, with Hispanics, those of African descent, and Asians leading the list, respectively. The American Academy of Facial Plastic and Reconstructive Surgery reported that rhinoplasty was the most common facial cosmetic procedure for both Hispanics and individuals of African heritage and was second only to blepharoplasty in Asian patients. Multiple factors have been attributed to this rise, including the increased socioeconomic status and improved social acceptance of plastic surgery among these ethnic groups. As the populations of United States and other industrialized nations continue to diversify, the number of ethnic rhinoplasties will surely increase.

Pertinent Anatomy

Anatomic descriptions in the plastic surgical literature, such as high dorsum, and low radix, traditionally refer to the ideal white (European) nose. However, this custom does not mean that characteristics described for a white individual's nose are the universal aesthetic ideal. Cultural norms and preferences dictate aesthetics: the model Asian nose differs from the model white nose. Nevertheless, the global pervasiveness of Western popular culture has made the ideal white nose a frequent goal for ethnic rhinoplasty patients.

Long ago, the term *Hispanic* described all people from the Iberian peninsula. Modern usage, however, describes only people from countries formerly colonized by Spain, including Mexico and various Caribbean, Central American, and South American countries. The term *mestizo* represents a subset of Hispanics with mixed European and American Indian ancestry. Neither term is fully inclusive of the other (Hispanics may be of pure Spanish ancestry, whereas mestizos may be of Portuguese ancestry), although the difference is semantic rather than clinically relevant. Nevertheless, Hispanic patients exhibit varied anatomic features unique to their individual Spanish and American Indian heritages.

At one end of the Hispanic spectrum is the so-called Castilian nose, with long nasal bones, a high dorsum, and normal tip projection. This represents primarily Spanish ancestry and is essentially a white nose. At the other end of the spectrum is the mestizo nose, with thick skin, wide alae, a retracted columella, an overall short nose, and a broad, underprojected tip. Any anatomic combination along this continuum may be seen, depending on the patient's specific genetic makeup.

The nose of a person of African heritage is characterized by a wide, low dorsum and a broad, underprojected tip. A wide piriform aperture splays the upper lateral cartilages and creates a broad middle vault. Thick skin and interdomal fat contribute to the bulbous tip. The medial and lateral crura are often short, thin, and weak. An acute nasolabial angle is caused by both an underrotated tip and bimaxillary protrusion. The nasal base is often wider than the interalar distance, and the underprojected tip contributes to excessive alar flaring.

The Asian nose typically has a low radix, low dorsum, and broad, underprojected tip. Thick, sebaceous skin contributes to a round tip with poor definition and blunted soft tissue triangles. The columella is commonly retracted. Asian patients frequently exhibit an acute nasolabial angle and retrusive premaxilla. Cartilages within the Asian nose tend to be weak, especially the caudal septum. The cartilaginous septum is frequently very small, necessitating the harvest of cartilage from a secondary location.

Preoperative Assessment

The surgeon elicits specific reasons for seeking rhinoplasty at the initial consultation and reviews the patient's cosmetic and functional concerns. It is vitally important to understand an ethnic patient's aesthetic goals. Some request cosmetic enhancements that preserve their unique ethnic characteristics; others will seek a more Western or white/European standard. Fastidious patients may voice their concerns using accurate terminology, whereas others will have difficulty identifying features they like and dislike. For the latter, photographs of desirable noses will help to focus the conversation.

Computer imaging is particularly helpful in these situations. A consensus can quickly be reached based on the visuals, and imaging facilitates discussion of realistically achievable results. For example, a petite nose will be unattainable in a black or mestizo patient with thick skin and a broad, underprojected tip. Imaging can demonstrate realistic, balanced results that will help the patient and surgeon develop an appropriate surgical plan.

Some patients express the desire to maintain their ethnicity, yet present photographs of a white person's nose. In the senior author's (D.M.T.'s) practice, Asian patients frequently provide photographs of Asian actresses, many of whom who have undergone prior augmentation rhinoplasties, rendering their nose more Western. Although they may ask for modest, ethnicity-preserving changes, they may be dissatisfied postoperatively if their dorsum has not been fully raised or their tip is left rounded and less refined.

Ethnic patients who request revision procedures must be screened for prior implants. Alloplastic implants are frequently used in Asia for augmentation rhinoplasty, particularly silicone L-strut implants. Implants can damage skin, particularly of the dorsum, leaving it thin, irregular, and telangiectatic. Silicone L-strut implants may also thin the tip skin, because the implant genu is the point of greatest tension. Implant removal frequently requires replacement with an autologous costal cartilage graft. This greatly increases the complexity of surgery and must be fully discussed with the patient.

The potential use of autologous grafting materials such as auricular or costal cartilage must be discussed with the patient preoperatively. If harvesting of costal cartilage is anticipated, knowledge of prior breast augmentation is important for both operative counseling and intraoperative technique. The scar from inframammary implant placement or breast reduction may be useful for costal cartilage harvest if it is still located within the inframammary fold.

The risks of costal cartilage harvesting and implantation should be carefully explained to the patient. In addition to the standard risks of pneumothorax, scarring, and graft warping, the patient should understand that he or she will have increased nasal stiffness postoperatively. This will soften over time, but the nose will always remain more rigid than it was preoperatively. Chest pain may range from nonexistent to moderate for 3 or 4 days postoperatively. Discomfort when lifting heavy objects may persist for 1 to 2 months before it subsides completely. Dorsal augmentation with costal cartilage in Asian patients stretches skin near the medial canthus, and changes to the epicanthal fold may occur.

Preoperative Planning

Multiple factors must be considered when designing the incision for costal cartilage harvest. The senior author preferentially harvests the sixth rib because of its position at the inframammary fold and less acute genu, which permits harvest of longer straight segments. Ribs five and seven may be accessed through the same incision when additional grafting material is needed. Fifth rib harvest can be more difficult, because it requires dissecting under the breast tissue in women and through the pectoralis muscle in men. The fifth rib has a more continuous curve than the sixth rib, making it difficult to harvest a long, straight segment. Seventh rib dissection frequently increases postoperative pain, because it constitutes a variable portion of the rib cage free margin, depending on the length of the eighth rib. Removal may cause a slight but noticeable depression and can potentially produce a less stable rib cage.

In women the incision is ideally placed in the inframammary fold. The right side of the chest is preferred for a right-handed surgeon; thus the patient's rib pain will not be confused with cardiac pain. In larger-breasted women, an incision can easily be hidden in the inframammary fold. If future breast augmentation is a consideration,

the incision should be made lower to anticipate the new inframammary fold. In some women the incision should be placed slightly more lateral so that it is not visible when the woman is wearing a dress with a low neckline. In patients with breast implants, the inferior extent of the breast pocket must be determined before the incision is made to prevent implant injury or violation of the implant capsule.

The size of the incision depends on a number of factors. Asian patients scar poorly on the chest, so incision length and placement are critical to a favorable outcome. Muscular or obese patients and those with pectus excavatum require larger incisions to accommodate the greater depth of dissection needed; in thin patients with superficial ribs, smaller incisions are required. Longer incisions are necessary for harvesting longer pieces of rib. Incisions as small as 1.2 cm can be used to harvest 4 or 5 cm of rib in patients with the appropriate chest characteristics. Harvesting rib through a small incision is more difficult and time consuming but is a cosmetically superior approach. Surgeons with less experience harvesting costal cartilage should use a larger incision to avoid damaging the pleura.

Operative Technique

The procedure is typically performed with the patient under general anesthesia in the supine position; the patient's head is placed on a small soft support, such as a doughnut. We prefer to use general anesthesia with endotracheal intubation to protect the airway from blood that may drip down to the larynx during the septoplasty portion of the operation. We typically prepare the ear in case additional cartilage is needed. With secondary rhinoplasty or augmentation rhinoplasty, we will prepare the chest to allow costal cartilage harvesting if needed.

Harvest of Costal Cartilage

The septum is unlikely to provide sufficient grafting material for ethnic patients undergoing augmentation rhinoplasty; invariably, auricular or costal cartilage harvesting is necessary. Graft warping is a potential complication when using costal cartilage, but the risk can be mitigated with meticulous technique. Early graft harvest and sequential carving allows time for bending and warping tendencies to present and be managed intraoperatively.

Harvesting of costal cartilage can often be performed before opening the nose in ethnic patients because of the insufficient septal cartilage and the obvious need for grafting material to augment the nose. The skin is incised with a No. 15 blade, and the subcutaneous fat is sharply dissected. Ragnell or Senn retractors are used to expose the muscular fascia. Frequent palpation with a 27-gauge needle ensures a proper trajectory of dissection and identifies the bony-cartilaginous junction. The rectus sheath and pectoral fascia fuse to form the fascial sheath above the sixth rib. A cruciate incision is made through the fascia, and any muscle is bluntly dissected to expose the rib. Blunt dissection minimizes bleeding and postoperative pain.

The thick, fibrous rib perichondrium is excellent material for camouflaging grafts, especially when performing tip grafting and dorsal augmentation. The outer layer of rib perichondrium may be excised initially or removed once the rib is harvested. Larger sheets can often be harvested by excising the perichondrium first. The perichondrium is incised with a No. 15C scalpel; the smaller profile of the 15C blade permits greater visualization through a small incision. The perichondrium is then elevated from lateral to medial with a Freer elevator, and the pedicle is divided with scissors after sufficient material has been raised.

Shallow transverse incisions are made with a 15C scalpel near the bony-cartilaginous junction and as far medial as the patient's needs dictate. Leaving a thin rim of cartilage at the bony junction allows sharp edges to be rounded after the rib is removed. The incisions should be superficial to avoid violating the inner perichondrium and pleura. Costal dissection is easily performed with the sharp end of the Freer elevator. Younger patients have soft, white costal cartilage, whereas older patients have yellow-brown cartilage with varying amounts of calcification. Often there are islands of calcification at the rib periphery, and dissection must proceed around them. Rarely is the entire segment calcified and unusable.

When freeing the perichondrium from the superior and inferior edges of the rib, it is best to err slightly into the rib itself. Leaving a thin cuff of cartilage helps prevent inadvertent transection of the often-attenuated deep perichondrium. There is frequently an interchondral joint between the sixth and seventh ribs near the rib genu.

The attachment may be fibrous, a synovial joint, or a solid cartilaginous connection that requires division with a Freer elevator. After the rib has been dissected circumferentially, the Freer elevator is used to bluntly elevate the rib off the deep perichondrium. The undersurface of the rib and the deep perichondrial sleeve can be viewed directly to ensure that the pleura is not violated. Significant resistance when trying to bluntly elevate the rib often indicates incomplete dissection at one of the corners, especially medially, where the rib is thicker. Care must be taken when elevating an older, more brittle rib to ensure that it does not fracture. After the rib is freed, a double-pronged skin hook facilitates removal from the pocket. The medial and lateral rib edges are trimmed and smoothed with Takahashi forceps. The inner perichondrial sleeve is inspected and irrigated with saline solution; a Valsalva maneuver performed by the anesthesiologist confirms pleural integrity. The rib is placed in an antibiotic-infused saline solution.

Carving often begins after opening the nose. Carving is best performed on a flat carving block with a No. 10 blade. Toothed forceps provide a secure grasp of the rib; non-toothed forceps may eject grafts off the carving block. Carving the rib into three segments maximizes the number of useable grafts. The thickness of each segment varies according to the patient's needs. The central portion of rib often warps least. Outer segments have a fibrous component that causes greater warping in younger patients but helps maintain graft integrity in older, more brittle ribs. The segments are thinned initially and placed back into the antibiotic-infused saline solution.

Final cuts are made just before the grafts are placed. Carving the grafts in this manner allows warping tendencies to manifest intraoperatively and to be used for curved grafts. For example, dorsal grafts placed concave side down will lie flat after skin-soft tissue envelope compression, whereas lateral crural strut grafts can be placed convex side up to better support the airway. Older calcified rib is more difficult to harvest, carve, and suture but maintains the distinct advantage of warping very little. Younger cartilage is easy to carve and suture but can warp dramatically and is less predictable.

Incision Closure

Careful closure of the chest incision minimizes scarring and visibility of the scar. Unused pieces of costal cartilage are placed back within the perichondrial sleeve. The muscular fascia is closed with 3-0 PDS sutures, and breast tissue or subcutaneous fat is closed with 4-0 PDS. The breast is pushed medially and inferiorly in women to assess for puckering that represents improper dermal tethering to the deep closure. The epidermal edges in small incisions are often macerated by retraction. A No. 15 blade can be used to trim the wound edge up to, but not around, the incision apex; trimming circumferentially elongates the incision. The skin is then closed deeply with 5-0 PDS and cutaneously with a running locking 6-0 nylon vertical mattress suture. Local anesthetic is injected after closure is completed. Bacitracin ointment is applied, and the wound is covered with nonadherent gauze and a transparent dressing.

Harvest of Auricular Cartilage

Auricular cartilage is easily harvested through a postauricular incision placed on the pinna above the postauricular crease. This incision placement ensures that scars will not be visible and prevents blunting of the postauricular sulcus. The incision is carried down onto the posterior perichondrium, which may be harvested or left in situ. The entire conchal bowl can be harvested without changing the external auricular appearance; violation of the antihelix, however, will cause a cosmetic deformity.

Transauricular needles can help demarcate the area to be harvested. The cartilage is incised with a No. 15 blade and bluntly dissected from the anterior perichondrium with a Freer elevator.

Hemostasis of the anterior skin–perichondrial flap is obtained with bipolar cautery; judicious use prevents damage to the flap. The skin incision is closed deeply with 6-0 Monocryl and superficially with 5-0 fast-absorbing gut suture. A Penrose drain is trimmed and left exiting the inferior extent of the incision. A cotton bolster coated in antibiotic ointment is sutured through and through the conchal bowl with 3-0 nylon; the posterior bolster can be lassoed within the suture loop.

Elevation of the Skin Flap for an External Rhinoplasty Approach

Details regarding the incision and dissection are discussed in Chapter 56. Ethnic patients frequently require increased projection, and it may be prudent to place the transcolumellar incision slightly lower to accommodate eventual superior movement of the scar.

Dorsal Augmentation

Most ethnic rhinoplasties require dorsal augmentation, although some patients may present with dorsal humps that require reduction. The cartilaginous convexity is first reduced with a No. 15 blade. If a bony component of the hump exists, the cephalic extent of the reduction is perforated with a 2 mm straight osteotome placed perpendicular to the nasal bones. This maneuver creates a weak point for the 12 mm Rubin osteotome to exit through and counteracts the tendency for overreduction. Reduction of the dorsal hump often creates an open roof deformity that requires lateral osteotomies to close. High-low-high lateral osteotomies are performed with a 3 mm straight osteotome. Intermediate osteotomies are rarely needed, except for an extremely wide dorsum.

Thoughtful graft selection for dorsal augmentation can help minimize postoperative complications. Septal cartilage is often preferred over auricular or costal cartilage for dorsal augmentation, because it does not curl or warp. Unfortunately, the septum is often insufficiently thick or is depleted and harvesting auricular or costal car-

58-1 Nasal dorsal augmentation

58-2 Dorsal hump reduction:
high horizontal dorsal osteotomy for more precise control

tilage is necessary. Auricular cartilage can curl at the edges and create a deformity when used for dorsal augmentation. The costal cartilage of older patients is typically brown and more calcified and brittle; although carving and suturing are more difficult, older costal cartilage warps less. Conversely, younger costal cartilage is white, softer, and easier to carve, but warps more.

Dorsal grafts are carved into a canoe shape: flat or slightly concave on the under-surface, gently rounded on the edges, and tapered at both the caudal and cephalic ends. The specific dimensions depend on the needs of the patient.

Ideally the dorsal graft is slightly curved so the graft can be set into position with the concave surface facing downward. This orientation protects against any chance that the graft will curve upward, leaving the patient with a prominence in the supratip and radix.

Graft edges often need camouflaging to prevent visible postoperative step-offs, especially in thin-skinned patients. Dorsal palpation is critical, since intraoperative edema will obscure minor irregularities. Perichondrium can be sutured along the graft edge with 6-0 Monocryl. Alternatively, the entire graft can be covered in perichondrium.

Graft size and placement are individualized for each patient. Greater dorsal augmentation creates a narrowing effect on the frontal view that must be balanced with anticipated changes to the tip. Ethnic patients frequently have wide tips that resist significant narrowing and necessitate restrained dorsal narrowing to preserve tip-dorsum harmony.

The radix of white/European individuals commonly lies between the superior lash line and the upper lid crease, whereas the radix of Asian patients typically lies at the midpupillary level. Dorsal graft placement thus depends on the degree of ethnic characteristics the patient wishes to maintain.

In primary augmentation rhinoplasties, dissection of a narrow dorsal pocket facilitates tight graft placement. For grafts extending over the bony dorsum, graft adherence can be improved by roughly rasping the dorsum and suturing perichondrium to the graft's undersurface. This will create a bone-perichondrial interface that promotes graft adhesion in the early postoperative period. The graft can be secured caudally to the middle vault with 5-0 PDS.

In complex revisions, the L-strut may need to be reconstructed. After building the dorsal component of the L-strut with extended spreader grafts and a septal extension graft, a separate dorsal graft can be placed on top of the stable middle vault. Placing the dorsal graft on top of extended spreader grafts permits minor movement independent of the L-strut.

Removal of large alloplastic implants in patients undergoing revision procedures requires wider dissection and often results in a large pocket. Grafts can be sutured to adjacent soft tissue or transcutaneously using 6-0 Monocryl. In the rare patient in whom graft stability cannot be obtained with suture fixation, a transcutaneous threaded Kirschner wire can be drilled through the dorsal graft and into the underlying nasal bone. On postoperative day 7, the wire can be removed or clipped at the skin surface.

Tip Contouring

The tip in ethnic patients is often bulbous and underprojected, and lacking in definition. Frequently used techniques include cephalic trim of the lateral crura, dome binding and interdomal sutures, and shield tip grafting. Repositioning of the lateral crura is seldom performed, because it can accentuate the hanging ala commonly found in ethnic patients.

Slightly increased projection may be obtained with onlay tip grafts in selected ethnic patients with thin skin. These rectangular or elliptical grafts are sutured horizontally over the domes with 6-0 Monocryl to simulate the natural horizontal tip highlight. Soft cartilage, such as auricular or trimmed lower lateral cartilage, is ideal for this purpose, and approximately 1 to 2 mm of increased projection can be achieved.

Thick-skinned patients frequently require shield tip grafts with lateral crural grafts to increase projection, stretch the skin, and refine the tip. The shape of the shield graft simulates the divergent medial crura and domes. Shield grafts are sutured to the medial crura with 6-0 Monocryl. Large grafts creating substantial increases in projection (greater than 2 mm) are often supported with buttress grafts and/or lateral crural grafts. Both grafts maintain postoperative tip projection by preventing cephalic rotation of the shield graft once the skin–soft tissue envelope is sutured closed. Lateral crural grafts are sutured on top of the native lateral crura, whereas lateral crural strut grafts are sutured to the undersurface of the lateral crura. In addition to supporting the shield graft, lateral crural grafts smooth the transition from the tip to the alae and preserve the natural tip-alar highlight. Shield tip grafts can be carved from any type of cartilage, although stronger septal and costal cartilage is preferred to weaker, more flexible auricular cartilage.

Tip refinement can often be obtained with dome binding and interdomal sutures. When a shield tip graft is used, the tip width is set by the leading edge of the graft. Soft tissue or perichondrium can be placed over and around the tip graft to provide additional camouflage.

Patients of African descent in particular have a large amount of fibrofatty tissue within the tip. This can be cautiously resected to increase tip definition; care is taken not to injure the subdermal plexus of the skin flap.

Weak alae can be supported with alar rim grafts. Rim grafts are thin, sliver-shaped grafts inserted into pockets dissected caudal to the marginal incision. They are secured with a single 6-0 Monocryl suture, and the medial edge of the graft is crushed with Adson-Brown forceps to prevent visibility within the tip. Rim grafts help form a triangular base by straightening concave alae. Correcting alar concavities eliminates shadows that isolate the tip and interrupt the tip-alar highlight.

The transcolumellar incision is closed deeply with a single 6-0 Monocryl to align and reduce tension on the skin edges. The skin is then closed with interrupted vertical mattress 7-0 nylon sutures oriented perpendicular to the incision. The marginal incisions are closed with 5-0 chromic gut, and the septal mucoperichondrial flaps are reapproximated with a 5-0 plain gut quilting suture.

Reduction of the Alar Base

Alar base reduction, if necessary, is the final step during rhinoplasty. Different intraoperative maneuvers have variable effects on the final alar position. For example, increasing tip projection decreases flare, whereas lateral crural repositioning increases flare. Regardless, ethnic patients frequently benefit from some form of base reduction. The degree of flare, nostril size, and native alar/sill anatomy determine incision placement. The noses of thick-skinned mestizo patients or individuals (particularly males) of African descent frequently have a smooth, rounded internal ala-to-sill transition. Base reduction incisions made across the nostril sill are at a high risk for visible scarring. These patients are better candidates for external alar reductions unless the nostrils are very large. Patients should be counseled preoperatively that their thick, sebaceous skin makes them more likely to scar unfavorably.

The amount to be resected is first outlined with a marking pen. Conservative excisions are preferable, because additional ala can be excised postoperatively at a later time. The ala is excised with a No. 11 blade. The incision is closed deeply with a single 6-0 Monocryl suture, and the skin is closed with interrupted vertical mattress 7-0 nylon sutures. Meticulous technique is necessary to prevent visible scarring.

Problems and Complications

Close postoperative follow-up is important after augmentation rhinoplasty to monitor the dorsal graft. Mild graft warping or shifting can be treated with nasal compression exercises for 1 minute 10 times daily until the graft position stabilizes. Severe warping or migration necessitates operative revision.

Dorsal irregularities are often camouflaged by thick skin in ethnic patients. Small visible bumps can be treated with a needle shave in the office. The area to be treated is first marked and then injected with a local anesthetic. A 16-gauge needle is inserted, and the bump is rasped with the needle's bevel. Depressions, unfortunately, cannot be treated in this manner. Revision surgery is needed to fill the depression with cartilage or soft tissue grafts.

Wide, underprojected tips are susceptible to postoperative loss of projection if not properly stabilized. Correction requires operative revision to stabilize the nasal base. Grafting material is needed to place a caudal septal extension or replacement graft to which the lower lateral cartilages can be secured.

The thick skin of many ethnic patients can cause prolonged postoperative edema. This can be especially problematic in the supratip area, where edema can lead to scar formation and create a polly-beak deformity. Edema that has persisted 4 weeks after surgery can be treated with nightly nasal taping. Recalcitrant edema can be treated with injections of 0.2 to 0.3 ml triamcinolone acetonide 10 mg/ml.

Pneumothorax can occur during rib graft harvest. Meticulous technique, especially blunt dissection within the perichondrial sleeve, is the best defense against this morbid complication. If a pleural tear is discovered intraoperatively, a red rubber catheter can be inserted into the defect. The wound should then be closed with the catheter in place. After closure, a Valsalva maneuver can be performed as the catheter is withdrawn to remove as much air as possible. A postoperative chest radiograph can confirm the presence of any residual pneumothorax and help to determine whether chest tube placement is necessary.

Scarring of the columella, alar base, and chest is more common in thick-skinned ethnic patients. Asian patients in particular scar poorly on the chest. Three weeks after surgery, patients are given Silastic sheeting to place on their incisions each night. The compression from the Silastic is thought to enhance the scar's appearance. Triamcinolone acetonide injections can also be used to treat hypertrophic scarring.

Results

This 37-year-old woman requested correction of her nasal deformity and left nasal obstruction. The frontal view revealed a narrow dorsum, wide tip, prominent infratip lobule, and an underprojected chin. On lateral and oblique views, she had a dorsal hump, a hanging tip lobule, and an underprojected and underrotated tip. On basal view, she had columellar deviation to the left, a flared right footplate, and nostril asymmetry. Intranasal examination revealed a left septal deviation.

Surgical Plan

The surgical plan for this patient was to perform an external rhinoplasty approach. She had a hanging tip lobule and underprojected tip, so stabilizing her nasal base was very important. She had a very small segment of septal cartilage; costal cartilage would provide material to graft her nose and augment her tear trough. Auricular cartilage was an option but would have required using both ears. A caudal septal extension graft was used to support the base, shorten the nose, and rotate the tip. Extended spreader grafts were used to stabilize the extension graft. Placement of a small radix graft and dorsal hump reduction helped improve her profile. Repositioning the lateral crura helped to improve the alar-columellar relationship. Her rhinoplasty worksheet details the maneuvers performed during the surgery.

 Inverted-V midcolumellar incision connected to bilateral marginal incisions
 Open septoplasty and septal cartilage harvest
 Dorsal hump reduction and rasping
 Bilateral lateral osteotomies
 Costal cartilage spreader grafts
 Bilateral cephalic trimming of lateral crura
 Costal cartilage caudal septal extension graft sutured to spreader grafts

Bilateral septal cartilage lateral crural strut grafts, dome sutures, and lateral crura caudal repositioning

Interdomal suture and crushed cartilage over domes
 Crushed cartilage radix graft
 Bilateral costal cartilage alar batten grafts
 Full-thickness alar base reductions
 Bilateral transcutaneous lower lid blepharoplasty with fat repositioning and costal perichondrial grafts to the tear troughs

Nine months postoperatively, the patient has appropriate dorsal width and smooth brow-tip aesthetic lines. She has a narrower tip and more aesthetic alar-columellar relationship. On lateral view, she has a smooth dorsum and increased tip projection and rotation. Her basal view reveals a straight midline columella and improved nostril symmetry.

This 24-year-old man requested rhinoplasty; there was no nasal obstruction. On frontal view, he had a hanging infratip lobule and high alar insertions. On lateral view, he had a deep radix, a dorsal hump, and an underprojected tip. His basal view demonstrated a very slight columellar deviation to the right. Intranasal examination revealed a right posterior septal deviation.

Surgical Plan

The surgical plan was to improve the patient's profile by performing a dorsal hump reduction and increasing his nasal tip projection. Costal cartilage harvest was necessary to obtain enough cartilage to lower his nostrils. Auricular cartilage was an option but is generally less effective because it is weaker. A caudal septal extension graft was used to stabilize his nasal base and prevent postoperative loss of tip projection. Correction of his flared nostrils was achieved by placing lateral crural strut grafts and repositioning the lateral crura more caudally. His rhinoplasty worksheet details the steps taken during the surgery.

Surgical Steps

Inverted-V midcolumellar incision connected to bilateral marginal incisions
Open septoplasty and septal cartilage harvest; two fractures within septal cartilage
Dorsal hump reduction and rasping
Bilateral lateral osteotomies to narrow upper third
Right chest incision and sixth rib harvest
Bilateral costal cartilage spreader grafts

Costal cartilage caudal septal extension graft overlapping left caudal septum
Bilateral cephalic trimming of lateral crura

Bilateral lateral crural strut grafts, dome sutures, and lateral crura caudal repositioning
Interdomal suture and crushed cartilage placed over domes
Crushed cartilage graft to infratip
Bilateral internal alar base reductions

Thirteen months postoperatively, the patient has an improved alar-columellar relationship as a result of moving his lateral crura to a more caudal position. On lateral view, he has a higher radix, lower dorsum, and increased tip projection and rotation. The patient has a very subtle residual dorsal convexity that looks appropriate in many male ethnic patients.

This 36-year-old woman requested rhinoplasty. On frontal view, she had a wide middle vault, nasal base, and tip. On lateral view, she had a dorsal hump, low dorsum, underprojected tip, acute nasolabial angle, and underprojected chin. Her basal view revealed a wide, underprojected tip with large, round nostrils.

Surgical Plan

The plan was to perform an open septorhinoplasty and stabilize the patient's nasal base. She had a very small segment of septal cartilage, and costal cartilage was harvested to provide adequate grafting material. A large caudal septal extension graft was needed to stabilize the base. A shield tip graft with lateral crural grafts was necessary to provide adequate tip projection. A radix graft helped align her profile. Chin augmentation helped balance her profile with the increased tip projection. Her rhinoplasty worksheet illustrates the steps performed during the surgery.

Twenty months postoperatively, the patient has a narrower middle vault, nasal base, and tip. On lateral view, she has a higher, smooth dorsum, increased tip projection and rotation, and increased chin projection. The basal view shows a narrower tip and nasal base.

This 23-year-old woman requested rhinoplasty. On frontal view, she had a very wide nose, ill-defined tip, and hanging alae. On lateral view, she had a low radix, low dorsum, an underprojected tip, and a retracted columella. The basal view revealed a very wide base and underprojected tip.

Surgical Plan

The surgical plan was to narrow the patient's nose by increasing the dorsal height with a dorsal on-lay graft. The abnormal, inverse alar-columellar relationship caused by the retracted columella and hanging ala required a large caudal septal extension graft to lengthen the columella. The lateral crura were not repositioned to avoid bringing down the alae. The shape of the lateral crura did not influence her nasal tip shape, so cephalic trimming was unnecessary. A shield tip graft was used to increase nasal tip projection and refine the tip. Alar base reduction was used to improve the width of the nasal base and nostrils. Her rhinoplasty worksheet illustrates the maneuvers performed during the surgery.

Surgical Steps

Bilateral dome sutures, tip graft, and lateral crural grafts covered in perichondrium

Bilateral alar rim grafts

Double-layer septal cartilage dorsal graft covered on margins with perichondrium

Full-thickness alar base reductions

Six months postoperatively, the patient has a narrower dorsum and tip and increased tip definition. Her columella is lower and presents a more aesthetic alar-columellar relationship. On lateral view, she has a higher radix and dorsum, increased tip projection, and increased columellar show. The basal view reveals a narrower and more projecting tip.

The 28-year-old woman requested rhinoplasty. On frontal view, she had an amorphous tip. On lateral view, she had a low dorsum and an underprojected tip. Intranasal examination revealed a right septal spur.

Surgical Plan

The plan for this patient was to perform an augmentation rhinoplasty. She had a low, wide dorsum that is typical in the Asian patient. Costal cartilage was harvested to obtain material for dorsal augmentation. An alloplastic implant could have been used to avoid harvesting costal cartilage, but this patient did not want artificial material used in her nose. The dorsal graft was used to raise her dorsum and produce a narrowing effect on frontal view. A caudal septal extension graft stabilized the nasal base. A shield tip graft was used to project and narrow the tip. Her rhinoplasty worksheet illustrates the steps performed during the surgery.

One year postoperatively, she has a narrower dorsum and a narrower and more refined tip. The lateral view reveals increased dorsal height and tip projection. Her nasal starting point is close to her midpupillary line. The basal view shows increased projection and a more refined tip.

This 28-year-old woman requested correction of her nasal deformity. She had no nasal obstruction. On frontal view, she had a wide dorsum, tip, and nasal base. On lateral view, she had a low radix, a very low dorsum, and an underprojected tip. The basal view revealed a wide, underprojected tip.

Surgical Plan

The plan for this patient was to perform an augmentation rhinoplasty. She did not want an alloplastic implant, so costal cartilage was harvested. An extended columellar strut was used to stabilize the nasal base. A notch carved in the strut's base was integrated with the nasal spine to prevent movement. The strut was further stabilized with thin splinting grafts overlapping the caudal septum. To keep the dorsal graft midline, it was notched and integrated with the columellar strut. This maneuver is frequently unnecessary, because the dorsal graft can be sutured to the upper lateral cartilages. A shield tip graft and lateral crural grafts were used to provide tip projection and contour. Her rhinoplasty worksheet illustrates the surgical steps performed.

Surgical Steps

Two ribs were needed in this patient. A very large dorsal graft was used to augment her flat dorsum. The other rib graft was used for the septal extension graft and tip grafts.

Right inframammary incision and harvesting of the sixth and seventh ribs
 Inverted-V midcolumellar incision connected to bilateral marginal incisions
 Septoplasty and septal cartilage harvest

Caudal septal extension graft sutured to nasal spine
 Hole drilled in nasal spine with a 16-gauge needle
 Caudal septal extension graft secured to caudal septum with bilateral splinting grafts

Costal cartilage dorsal graft covered in perichondrium
 Notch carved in caudal aspect of dorsal graft and integrated with caudal septal extension graft
 Bilateral alar batten grafts

Shield tip graft and lateral crural grafts
 Crushed cartilage and perichondrium placed over tip graft
 Supratip graft placed

Six months postoperatively, she has a narrower dorsum and tip. On lateral view, she has increased dorsal height and tip projection. The basal view reveals her increased tip projection.

Concluding Thoughts

Ethnic patients requesting rhinoplasty frequently require increasing nasal tip projection or augmenting the nasal dorsum. They tend to have weak lower lateral cartilages and lack nasal tip support. Reductive methods may further decrease nasal tip support and leave the patient with inadequate refinement. Structural grafting can improve tip support and tip definition. Increasing the dorsal height can improve nasal dorsal definition and create a narrowing effect. Structural grafting may require harvesting ear cartilage or costal cartilage. Most ethnic patients have inadequate septal cartilage for grafting purposes. Costal cartilage will provide more than enough material for grafting but does require more advanced techniques. Management of the ethnic patient requires clear communication to ensure the patient and physician agree on the intended aesthetic changes.

Clinical Caveats

Requests for cosmetic procedures are increasing in ethnic patients; rhinoplasty is the most commonly requested.

Clear operative goals are necessary for patient satisfaction.

Careful planning of the chest incision minimizes morbidity.

Early and sequential costal cartilage carving allows warping tendencies to manifest intraoperatively.

Knowledge of cartilage curvatures is essential for proper graft selection and usage.

Stable dorsal graft placement prevents postoperative graft migration.

Base reduction is frequently necessary in ethnic patients.

Close postoperative follow-up is necessary for optimal results.

CHAPTER 59

Applied Anatomy of the Breast

KRISTIN A. BOEHM, FOAD NAHAI

As in every medical discipline, plastic surgery is continuously evolving. Over the years we have seen the development of more-complex techniques by less-invasive means with the goals of ever-improved results and longevity. But most of these refinements, published in the literature and touted at national meetings, focus on the surgical techniques themselves. Articles and texts are replete with procedural descriptions of new microvascular flaps for breast reconstruction or an individual author's stepwise instructions for fat grafting that maximizes survivability. Although most surgeons would agree that a fundamental knowledge of anatomy is a critical foundation to understanding and performing these new surgeries, the likely consensus is that the anatomic principles are more static than the procedures being developed from them.

Nevertheless, advances are being made in the field of breast anatomy as well. Improved techniques for study have led to the discovery of previously unknown structures, enhanced microscopic details, and even better understanding of anatomic variants. These new concepts can have clinical applications that may ultimately offer advantages to patients. In breast surgery, for example, the enhanced ability to localize the vascular and nerve supply to the nipple-areola complex has led to techniques that more reliably preserve these structures and minimize the risk of complications in this area.

So while we often use the term *basic anatomy*, the human form is extremely intricate, and our knowledge of it and its structures is ever evolving. Staying in the forefront of knowledge of anatomy is as important as embracing new surgical techniques in an effort to enhance patient care and deliver superior results.

Embryology

Any discussion of breast anatomy naturally begins with the development of the breast in utero. At the fifth or sixth week of development, mammalian breasts develop along the ventral side of the embryo in longitudinal bands of thickened ectoderm called *milk lines*. These milk lines extend from the axilla to the inguinal region. Most animals develop multiple pairs of breasts along the thorax and abdomen. Humans are distinct in that they develop only a single pair of glands on the thoracic portion of the milk line. This becomes evident at around 9 weeks' gestation, at which time the milk line regresses except for a small span in the pectoral region, where breast development will ultimately occur. Failure of this regression gives rise to polymastia, characterized by accessory mammary glands, and polythelia,

in which supernumerary nipples are present. The axilla is the most common location of extraglandular breast tissue, whereas additional nipples are most often found on the chest wall below the breast. Amastia, or the absence of a breast, is a rare congenital anomaly; it occurs as a result of an arrested mammary ridge at about the sixth week of fetal development.

The mammary gland develops as an invagination of ectoderm. Squamous epithelium essentially invaginates to form a primary bud, which in turn stimulates the development of 15 to 20 secondary buds. These epithelial extensions continue to grow and extend into the connective tissue of the chest wall. By 20 to 24 weeks' gestation, these invaginated epithelial cords develop lumina and will eventually form the lactiferous ducts. The surrounding mesenchyme will become the supporting structures of the breast.

At birth, the individual branched ducts drain into more major ducts, which then coalesce into shallow epithelial pits. These pits become elevated and transformed into the nipple. Failure to do so results in a congenitally inverted nipple; this occurs in 2% to 4% of individuals. During infancy and childhood, the supporting tissues of the breast and the ducts will grow along with the increase in body size. At puberty, hormonal stimulation will cause proliferation of glandular tissue.

Surface Anatomy

There is tremendous variation in the size and configuration of the mature female breast. The gland typically extends from the second or third rib down to the sixth or seventh rib, where the inframammary fold is defined. It extends medially from the sternocostal junction across to the anterior or midaxillary line. The superolateral part of the mammary gland extends toward the axilla, forming the axillary tail of Spence. Along its deep surface, the breast mound sits atop the fascia of the pectoralis major, serratus anterior, external oblique, and upper rectus muscles. The deep layer of the superficial pectoral fascia lies on the posterior surface of the breast. Between this and the deep pectoral fascia is a potential space called the *retromammary bursa*. This space is identifiable during mastectomy and allows a bloodless plane of dissection.

The breast assumes a conical form with a base usually measuring 10 to 12 cm and a thickness of 5 to 7 cm. Fat lobules confer a rounded contour to the breast; the deposition of fat and branching of the lactiferous ducts that occur at puberty lead to breast enlargement. By contrast, the decrease in adipose and glandular tissue that accompanies aging can give a flaccid, pendulous configuration to the breasts of elderly women.

The nipple-areola complex consists of pigmented, stratified squamous epithelium. The complex typically measures 2 to 3 cm in diameter, and although its position is variable, ideally it is located in the center of the breast mound. The areola contains sebaceous glands, sweat glands, and visibly elevated accessory glands called *Montgomery's tubercles*, which provide lubrication during lactation. Beneath the skin of the areola, smooth muscle fibers are arranged radially and circumferentially as well as longitudinally along the lactiferous ducts up to the nipple. These muscles respond to tactile as well as autonomic sympathetic stimulation and are responsible for nipple erection and areolar constriction. The entire complex, particularly the nipple, has a rich sensory innervation that is important during lactation and milk letdown.

Glandular Anatomy

The 15 to 20 lactiferous ducts extend from deep within the breast lobules and terminate as openings in the nipple. These ducts define the lobes of the breast, each of which consists of all the lobules and alveoli that drain into a single excretory duct. In the subareolar tissue, each lactiferous duct dilates to form a lactiferous sinus. The ducts are lined with stratified squamous epithelium and gradually transition to a double layer, then a single layer of cuboidal cells toward the nipple.

Each duct drains 15 to 20 breast lobules. The lobule is the functional unit of the breast. Each lobule drains from 10 to 100 alveoli. The walls of the alveolar ducts consist of an inner layer of columnar glandular cells overlying a stratum of myoep-

ithelial cells. Connective tissue surrounds the lobules, but there is no distinct fascia separating the lobules. The stroma surrounding the lobules contains lymphatic vessels that bring lymph to the collecting ducts. Adipose tissue around the lobules accounts for most of the mass of the breast. There is a defined subcutaneous layer between breast tissue and the overlying skin, and this is often used as a plane of dissection in mastectomies. Most of the glandular tissue is found in the central and upper portions of the breast mound, particularly the upper-outer quadrant. This probably accounts for the higher incidence of breast cancer in this region.

The breast is enveloped by skin and subcutaneous tissue, but no true fascial layer. There are fibrous thickenings scattered between breast lobules and extending from the pectoral fascia to the overlying skin. These structures, known as the *suspensory ligaments of Cooper*, provide some structural framework to the breast parenchyma. These ligaments have a degree of laxity and stretch to them that allows breast mobility while maintaining structural integrity. Such factors as weight fluctuation, pregnancy, and aging can attenuate these ligaments and lead to mammary ptosis. On the other hand, breast malignancies can surround and shorten these ligaments, causing the dimpling of the skin known as *peau d'orange*.

Although Sir Astley Cooper was probably one of the first anatomists to delineate the internal support structures of the mammary gland, others have described additional ligaments that aid in breast suspension. Biesenberger described the *ligamentum suspensorium mammae*, which starts at the clavicle and reaches to the upper border of the breast and the retromammary space. His work, as well as more recent anatomic study, confirms the great variety in the development of this ligament: it is

a rather robust and well-defined structure in some individuals, yet almost indistinct in others. This may well correlate to the individual development of ptosis in some women but not in others.

Intraoperative experience, particularly with implant insertion, has demonstrated a fibrous bridge between the pectoralis muscle and the skin of the inframammary crease. This inframammary crease ligament gives rise to the inframammary fold and acts as a sling for the breast parenchyma. Cadaver studies have elucidated the relationship of the inframammary crease ligament to the underlying bony framework. The ligamentous structure was found to be continuous with the fifth rib medially and the fascia between the fifth and sixth ribs laterally. Histologic sections show the presence of fibrous tissue abutting rib perichondrium. Medially this structure seems to be a condensation of the rectus abdominis fascia and laterally the fascia of the serratus anterior and external oblique muscles. The firm and fixed nature of this structure, particularly in comparison to Cooper's ligaments, has clinical relevancy. During an augmentation mammoplasty, release of the pectoralis muscle with preservation of the ligament to the bony framework will minimize the risk of the breast's bottoming out. In reconstructive surgery, maintaining the integrity of this structure helps to create a more natural breast and maximize symmetry with the contralateral breast.

Further investigation has demonstrated a horizontal septum at the level of the fifth rib that traverses the glandular tissue. This septum thickens along the medial and lateral edges and curves upward into vertically oriented ligaments that attach the breast to the thoracic wall. These ligaments appear to have a superficial and a deep component; medially they connect to the inframammary crease ligament and laterally to the axillary fascia. Tension on these structures acts as an internal brassiere that lifts the breast superiorly. By corollary, decreased elastin in these ligaments or their stretching over time probably contributes to loss of shape and firmness. Thus knowledge of these ligament locations and variations is important as we continually look to newer and longer-lasting techniques to address mammary ptosis.

Microscopic Anatomy

In response to the hormonal stimulus of puberty, the layers lining the ducts and alveoli increase in number and form additional buds. The mature female breast has three cell types lining the ducts: superficial A cells, basal B cells, and myoepithelial cells. The A cells contribute to milk production. They are rich in cytoplasmic RNA and ribosomes within the cytoplasm. B cells, also known as *chief cells*, are abundant and provide energy for the luminal secretory cells. Myoepithelial cells contain myofila-

ments and perform a contractile function. They surround the alveoli of the milk duct and contract in response to sex steroids and prolactin. This provides the mechanism whereby a milk-filled alveolus can empty into the milk ducts and ultimately up toward the lactiferous sinuses.

Hormonal Regulation

Breast growth, development, and function occur in response to a variety of hormones and growth factors. Intracellular receptors and cell membrane receptors allow binding of these substances, which in turn triggers physiologic responses in the tissues.

Estrogen is the principal hormone responsible for breast growth and maintenance. Because it is lipid soluble, estrogen can diffuse through the cell membrane of both normal and malignant breast cells, where it binds with estrogen receptors. This complex initiates messenger RNA (mRNA) transcription and subsequently protein translation. This mechanism mediates ductal maturation, metabolism, and new receptor development. The result is proliferation of ductal epithelium, myoepithelial cells, and surrounding stroma. The drug tamoxifen prevents the binding of hormones to target receptors, thereby inhibiting the growth of estrogen receptor-positive mammary tumors.

Released from the ovaries, progesterone contributes to lobular development. It initiates the formation of the secretory components of the mammary epithelium, located at the terminal aspects of the ductules. Both progesterone and estrogen can increase connective tissue and fat in the breast, thereby leading to the rounded form of the fully developed breast. Gonadotropic-releasing hormone from the hypothalamus stimulates the release of leuteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary. LH and FSH are responsible for ovarian synthesis and release of progesterone and estrogen, respectively.

Prolactin acts synergistically with estrogen in ductal development and with progesterone in lobuloalveolar development. It is the hormone responsible for lactogenesis in the postpartum period. Cortisol and insulin are required along with prolactin to differentiate alveolar cells into milk-secreting cells. Prolactin is secreted by the acidophilic cells of the anterior pituitary at parturition.

The menstrual cycle is characterized by alternating levels of hormones. In the premenstrual phase, rising levels of LH and FSH contribute to a rise in estrogen. After ovulation, estrogen levels continue to increase and progesterone rises. These elevated hormones cause an increase in breast volume from water retention, increased base-

ment membrane thickness, ductal dilation, widened alveolar diameter, and increased intraalveolar secretions. After the onset of menses and withdrawal of sex steroids, the breast volume decreases in response to edema regression, reduction in glandular and alveolar cell size, and diminished secretions.

With pregnancy, high levels of estrogen and progesterone are maintained, initially by the corpus luteum, and, after the twelfth week of gestation, the placenta. In the first trimester, estrogen causes the ducts and lobules to proliferate. Glandular epithelium replaces fatty tissue. The latter part of the first trimester is characterized by breast enlargement, venous dilation, and increased pigmentation of the nipple-areola complex. In the second trimester, the secretory epithelium becomes active in response to progesterone. By the third trimester, colostrum fills the alveolar and ductal spaces, accompanied by increased blood flow and enlargement of myoepithelial cells. Toward the end of pregnancy, prolactin circulates and initiates synthesis of milk fat and proteins.

Following delivery, the placentally induced sex steroids cease and the breast is influenced by prolactin. The milk released in the first few days after parturition, called *colostrum*, has a low lipid content but is rich in antibodies; 4 to 5 days after parturition, the milk becomes laden with lipids, protein, carbohydrates, and immunoglobulins. The ongoing secretion of prolactin by the anterior pituitary is necessary to sustain milk production and secretion. A nursing infant's tactile stimulation of the nipple-areola complex maintains this and will also initiate release of oxytocin from the posterior pituitary. Oxytocin causes myoepithelial cells to contract, which pushes milk from the lobules into the lactiferous ducts. The presence of milk in the ductal system provides an ideal culture medium for bacterial overgrowth. Obstruction to flow along the ducts, usually from areolar inflammation, leads to suppurative mastitis. With cessation of nursing there is regression of the extralobular stroma and atrophy of the formerly proliferative glandular and ductal elements. The breast usually returns to its prepartum state over the next 3 months.

During menopause, the body no longer produces sex steroids as a consequence of diminished ovarian function, and there is actual loss of glandular tissue. Adipose tissue can replace lobular elements, although there is usually a loss in total mass of fat volume in the breast. The result is decreased breast volume, and the breast takes on a flatter, more pendulous shape.

Blood Supply

Most of the breast mass receives its blood supply from the internal mammary artery. Branches of this artery must pass through the intercostal muscles along the second to fifth ribs, a few centimeters lateral to the parasternal border. Once these ventral branches enter the breast, they collateralize with two other major sources of blood supply: the lateral thoracic artery and the cutaneous branches from the posterior intercostal arteries. The lateral thoracic artery originates from the axillary artery and traverses along the lower border of the pectoralis minor muscle. Along its course of the muscle, the lateral thoracic artery gives off the external mammary artery, which will eventually come ventrally through the muscle to supply the upper-outer quadrant of the breast. Branches of the third through fifth posterior intercostal arteries supply the lower outer quadrant of the breast.

The veins parallel the arteries, with primary drainage into the axilla. Significant veins include the perforating branches of the internal thoracic vein, tributaries of the axillary vein, and perforating branches of the posterior intercostal veins. A notable pattern of superomedial and inferior pole drainage appears responsible for the bulk of venous drainage. Although the dominant drainage route appears to be through the third and fourth intercostal spaces, superomedial drainage to the second and third intercostal spaces and lower pole drainage to the fourth and/or fifth intercostal space have been consistently identified and appear to represent anatomic norms.

Although venous anatomy is less explored than arterial anatomy, most vascular compromise encountered during breast reduction surgery results from venous compromise. This underscores the importance of maintaining venous architecture in breast surgery to minimize complications. Developments in infrared photography have helped to elaborate the venous architecture of the breast. A subareolar plexus has been identified, with venous radiation from this plexus, probably to the deep venous structures. Preservation of this plexus with deepithelialization techniques should theoretically minimize the risk of venous outflow problems in breast surgery by maintaining a connection between superficial and deep vessels.

Relatively recent cadaver studies have reinforced these well-established vascular patterns, but more closely pinpoint location and demonstrate a consistent anatomic course for the supplying vessels. A horizontal fibrous septum has been shown to arise from the pectoralis fascia at the level of the fifth rib, similar to an intestinal mesentery. This septum lies in between a cranial and caudal vascular network and courses toward the nipple-areola complex. The cranial portion carries inflow from the thoracoacromial artery at the level of the fourth intercostal space and a branch of the lateral thoracic artery. The caudal network is supplied by perforating branches from the fourth and fifth and occasionally sixth intercostal arteries. Along the breast borders, this septum coalesces into medial and lateral ligaments, attaching the breast to the sternum and pectoralis minor, respectively. Medially, the ligament contains perforating branches from the internal thoracic artery, across the second to fourth intercostal spaces. Laterally, branches off the lateral thoracic artery from the second to the fourth intercostal spaces are found.

These vessels within the septum essentially bisect the breast into cranial and caudal parts. This division may well be rooted in embryology, with the formation of cranial and caudal ingrowths of ectoderm separated by a mesenchyme that ultimately forms the vascular network. Histologically, the glandular tissue in these two parts is identical. However, there is clinical significance to this anatomy, particularly as it relates to breast reduction surgery and the goal of maintaining the blood supply to the nipple-areola complex. This has led to the development of the septum-based mammaplasty popularized by Hamdi and colleagues that consists of a two-part glandular resection both above and below the septum. The remaining pedicle maintains the septal attachment of the gland to the thorax. Because this septum contains the vascular perforators, the blood supply to the pedicle and nipple-areola complex is maintained, and the risk of fat necrosis and nipple loss is minimized. Additionally, because this technique maintains a dual blood supply to the pedicle, with inflow both medially and laterally via the septum, more lateral breast resection can be performed, which is often an area of preoperative concern for patients.

Innervation

Sensory innervation to the skin overlying the breast is principally derived from lateral and anterior cutaneous branches of the second through sixth intercostal nerves. A portion of skin along the superior pole is also supplied by branches from the supraclavicular nerve, off of the cervical plexus. The lateral branches of the intercostal

nerves exit through the intercostal spaces to supply the breast. The third through sixth branches are known as *lateral mammary branches*. The lateral branch of the second intercostal nerve is the intercostal brachial nerve and supplies the upper medial aspect of the arm and axilla.

Of utmost importance to plastic surgeons is preservation of the sensitivity of the nipple-areola complex. The fourth lateral cutaneous branch has long been held to be the most important nerve for sensation to the nipple. Its course, however, is somewhat more controversial, largely because of the difficulty in dissecting this small nerve as well as its anatomic variations. Schlenz et al performed a relatively large number of cadaver dissections to confirm the importance of the fourth lateral intercostal nerve, which supplied the nipple in 93% of specimens. They showed that while a superficial course of the nerve exists as a variant, the overwhelming majority of the time the lateral cutaneous nerve takes a subglandular course within the pectoral fascia to approach the nipple from the posterior surface. Resections at the base of the breast are therefore more likely to jeopardize sensation to the nipple-areola complex.

Medial nipple innervation is most commonly derived from anterior cutaneous branches of the third and fourth intercostal nerves. Unlike the lateral counterparts, these nerves take a more superficial approach in the subcutaneous tissue and become more superficial as they reach the medial areola. Incisions around the medial areolar edge are therefore more likely to injure these nerves.

The same septum that carries the vascular network to the nipple-areola complex also guides the main nerves to the nipple. Overwhelmingly, this consists of a deep branch of the lateral cutaneous branch off the fourth intercostal nerve. The nerve consistently runs down the fibrous septum along the retromammary space from lateral to medial, passing through the gland to redirect toward the nipple. Once again, preservation of the septum in breast surgery procedures will maximize the chances of maintaining sensation in the nipple-areola complex.

Lymphatic Drainage

The majority of lymphatic flow from the breast is into the axilla; the remainder of flow is through the internal mammary nodes. This anatomy is reflected in the tendency of breast cancer to involve axillary nodes. Both the axillary nodal groups and the internal mammary nodal group are pathways for the metastatic spread of breast cancer to the systemic circulation.

The lymph nodes within the axilla are divided into three levels based on the location of the nodes relative to the pectoralis minor muscle. Level I nodes are lateral to or below the level of the lower border of the pectoralis minor muscle. This group includes the external mammary, axillary vein, and scapular lymph nodes. Nodes deep to or behind the pectoralis minor muscle are level II lymph nodes and include the central lymph node group and the subclavicular nodes. Nodes above the upper border of the pectoralis minor muscle are level III; the subclavicular and apical node groups contribute to level III.

Lymphatic drainage from the breast can occur by lateral, medial, transpectoral, and retropectoral routes. The lateral route is the most important. The majority of breast and breast skin lymph will drain laterally through the external mammary node group. Lymph that drains medially will drain via the parasternal lymphatics and ultimately into the internal mammary lymph node chain. The lymph that drains medially can originate from all quadrants of the breast and is not limited to the medial aspects of the breast. Transpectoral drainage is via Rotter's nodes, which are located beneath the lateral aspect of the pectoralis major muscle. Rotter's nodes will drain into lymphatics along the thoracoacromial artery to the subclavicular group of level III. The final route of drainage is retropectoral, in which the superior and internal aspects of the breast drain into lymphatic vessels located along the lateral and inferior portions of the pectoralis muscles and eventually terminate in the subclavicular node group in the axilla.

The development of breast lymphatic mapping has assumed greater importance as the sentinel lymph node biopsy in breast cancer has become the standard of care. The vastness of the lymphatic system poses a challenge, and until recently most knowledge of breast lymphatic anatomy was derived from gross clinical studies dating back to antiquity. More modern techniques incorporate injection, cross-sectional analysis, and radiography to elucidate lymphatic structures. These methods verify that lymph-collecting vessels along the anterior torso drain preferentially into the axillary lymph nodes. The previously held dogma relating breast lymphatics to upper torso lymphatics was that the two were connected by a subareolar plexus that ultimately drained into the axilla. Undoubtedly this is the case for some lymph channels located within breast parenchyma. However, it appears that there are also some lymphatics that drain breast tissue without passing through the subareolar plexus and instead drain directly into the axilla. Additionally, there are perforating lymph vessels that course beside the branches of the internal mammary vessels and drain into the ipsilateral internal mammary lymphatics. In some studies, one sentinel node in the axilla drained almost the entire breast. In most, more than one sentinel node is represented.

The prevalence of breast cancer and now-standard performance of sentinel lymph node biopsy raises the question of whether transaxillary breast augmentation interferes with breast lymphatic drainage patterns and ultimately the detection of cancer. Lymphoscintigraphy has been employed to evaluate lymphatic patterns in patients immediately before, immediately after, and in the long term following transaxillary breast augmentation. No statistically significant differences in patterns or time of uptake have been identified among the subjects at the various time intervals. The accepted consensus is that preserved axillary drainage patterns from the breast allow successful sentinel lymph node biopsies in those who later require this procedure after a transaxillary augmentation.

Concluding Thoughts

Performing safe and high-caliber surgery of the breast, aesthetic or reconstructive, requires thorough knowledge of its structures. The study of breast anatomy continues to be of clinical importance as newer techniques for breast surgery evolve.

Clinical Caveats

Continued research and technique refinements have enhanced our knowledge of breast anatomy and the breast's structural framework.

In particular, the concept of an internal breast septal system has been shown to consistently predict neurovascular structures that are important to preserve in all types of breast surgery.

Appreciation of this septal system may help to formulate surgical techniques that reinforce such a structure in attempting to correct mammary ptosis and the bottoming out phenomenon.

Understanding both the established and newer tenets of breast anatomy is important to be able to effectively examine, diagnose, and surgically treat conditions including breast cancer, hypomastia, macromastia, mammary ptosis, and congenital breast deformities.

CHAPTER 60

Clinical Decision-Making in Breast Surgery

FOAD NAHAI

Although only breast reduction actually treats or improves any symptoms, I consider any operation on the female breast to be an aesthetic procedure—not only augmentation and mastopexy, but also reduction and reconstruction. Whether we are restoring body image and self-confidence in a woman who has lost a breast, or enhancing the appearance of a “normal” breast in an effort to boost a woman’s self-confidence, our goals are the same as for any aesthetic procedure.

Principles of Breast Aesthetics

Breast aesthetics consist of the “four S’s”:

Shape

Size

Symmetry

Scars

Shape and Size

Breasts come in all shapes and sizes, some more aesthetic than others. Although the ideal size will vary according to personal and cultural preferences, there is more consensus on what constitutes the ideal shape. I believe shape to be of the utmost importance. The ideal aesthetic breast is projecting, with adequate volume above and below the nipple-areola complex, more below than above. The nipple-areola complex should be located at the point of maximal breast projection. Although breast size is subject to individual taste and societal preference, and is too often influenced by media images, it is also true that disproportionately large or small breasts do not complement a woman’s figure. They may also have physical ramifications. Careful counseling is required when a thin, 5 feet 4 inch, 100-pound woman requests a D cup breast size. Conversely, a well-proportioned teenager whose body development is advanced beyond that of her peers may seek breast reduction to avoid what she feels is unwanted attention.

Symmetry

Ideally, a woman’s breasts are uniform in color and symmetrical in size, shape, and nipple-areolar position. Although minor asymmetry is the rule rather than the exception, gross asymmetry is not only distracting but of practical importance to a woman in terms of bra cup size and appearance in clothing. When a surgeon is counseling a woman seeking breast surgery, minor asymmetries of her breasts must be pointed out. Most women are very accepting of these asymmetries preoperatively, but this is not the case after aesthetic breast surgery.

BREAST SHAPES AND SIZES

Scars

Although many patients' perception is that plastic surgery means no visible scars, in reality that is not possible. Rather, our goals should be to keep the scars minimal in length and as inconspicuous as possible as we enhance the breasts' shape. There is no question that shape is far more important than scars. I believe that shortening of scars and maintenance of optimal shape are mutually attainable goals.

The following three women have had aesthetic breast surgery. They each demonstrate ideal shape, appropriate size to match their bodies, and inconspicuous scars.

AUGMENTATION

MASTOPEXY

REDUCTION

How do we control shape, symmetry, size, and scars? Symmetry and size are related more to the surgeon’s judgment, artistic sense, and surgical skill than to operative technique. When breast implants are placed, the shape of the breasts is largely dependent on the dimensions, volume, and shape of the implant. Shape and scars, on the other hand, are very much dependent on operative technique. Optimal breast shape and minimal scars are possible through a variety of techniques.

Safety: The Fifth S

Breast aesthetics also consists of safety—not only of the patient, but also of the nipple-areola complex. Knowledge of the arterial blood supply and venous drainage of the breast, and specifically of the nipple-areola complex, is essential.

Breast Augmentation

Although the type of breast implants available may vary from one country to another, the principles of implant selection remain the same. The most important determinant of the aesthetic quality of the result is the size of the implant. Inappropriate size selection leads to problems with shape and the need for revision, especially with saline implants.

Patient Evaluation for Breast Surgery

Skin	Width (BW)
– Quality	Thickness (BT)
– Quantity	Suprasternal notch-nipple distance (SSN-N)
Parenchyma	Nipple-inframammary fold distance (N-IMF)
– Fatty	
– Fibrous	
Skin-parenchyma relationship	
– Tightly adherent	
– Moderately adherent	
– Loose	

Detailed patient examination and careful physical measurements will guide the surgeon in selecting the appropriate implant to optimize results and minimize the need for revisions. We must weigh the patient’s anatomic features and her desires for breast size in selecting implants, taking into consideration available implant sizes and dimensions in light of our own experience and judgment.

The examination of the patient includes breast measurements and an assessment of the breast parenchyma and skin, including the relationship of the skin to the underlying breast tissue. All of these anatomic features will influence implant selection as well as the choice of surgical approach and implant placement.

I prefer a dimensional approach to implant selection rather than the volume approach, where the surgeon, through judgment or a desire to please the patient, selects an arbitrary volume for the implant. The most important measurements in selecting the implant are the breast width (*BW*) and breast thickness (*BT*). *BT* should be measured in the upper pole. My preference is to measure it along the *SSN-N* line. (Other measurements shown include *AW*, areolar width; *MC-A*, midclavicular to areola; *N-IMF*, nipple to inframammary fold; and *SSN-N*, suprasternal notch to nipple.) *BW* minus *BT* will indicate the maximum implant width for that breast. Charts are available from all implant manufacturers clearly depicting the diameter, projection, and volume of their implants. Once the base diameter of the implant has been decided on, projection and volume can be selected based on that diameter. If a moderate profile implant would not accommodate the volume or projection desired for the patient, a high profile implant may be selected that will allow more volume and projection with the same diameter. This dimensional approach to implant selection allows maximal projection without exceeding the height and width limits of the breast.

Anatomical or shaped implants demand more precise and detailed measurements to ensure that the appropriate shape, height, and projection are selected.

A moderate profile implant is shown. With increasing volume, the implant extends beyond the width of the breast without increasing projection.

In contrast, a high profile implant increases projection with increasing volume without extending beyond the width of the breast.

Implant Options

Implant options include the following:

- Size
- Shape
- Shell
- Filler

Breast implants are offered in a variety of sizes, shapes, shell surfaces, and filler materials. Size options include dimensions, width, height, and projection as well as fill volume. Prefilled implants do not offer the flexibility of on-table volume adjustments; however, most saline implants and double-lumen implants do offer this option.

The majority of available implants are round, with variations in projection. Standard or moderate profile implants project less than high profile ones. Anatomic-shaped implants are gaining popularity for primary breast augmentation, especially with the cohesive gel implants that are now available. Although currently most anatomic implants are for breast reconstruction and round implants are for augmentation, anatomic implants may well become surgeons' first choice for breast augmentation, especially in thin women. Although the movement of round implants within the pocket does not pose any risk of breast shape change, anatomic implants must be positioned precisely, and any movement will lead to distortion of breast shape. Most if not all currently available anatomic implants are textured to reduce this risk.

The surface of the implant may be smooth or textured. At one time, polyurethane-covered implants were very popular in the United States, and in fact, led to the development and popularity of the textured-surface implants. Polyurethane-covered implants are currently available in some European and South American countries. Although the polyurethane covering of the implants is textured in appearance, this covering is biologically active, becoming incorporated into the surrounding capsule, unlike the standard textured silicone surface. My preference with saline implants is a smooth surface rather than textured, because I have found less visible and palpable rippling as well as a lower implant failure rate with a smooth-surface implant.

Our current options for implant fillers are limited to saline and silicone gel. Other materials have been investigated but have not proved to have any advantage over gel or saline. Some, such as the soybean oil implants, have been withdrawn from the market. Although the saline implant remains a popular option for breast augmentation in the United States, gel-filled implants are preferred in most of the rest of the world. A variety of cohesive gel-filled implants are available and under development, and I believe gel-filled implants will become the filler of choice in the very near future. The advantage of cohesive gel is that in the event of implant failure, the gel will not migrate. The cohesive property also enhances the maintenance of shape in the anatomic implant.

Although saline as a filler is completely biocompatible without any side effects in the event of leakage, it falls far short of the ideal filler in terms of feel, consistency, and pliability. It also appears to have a more deleterious effect on surrounding tissues in terms of thinning and stretching of the skin envelope than its gel-filled counterparts.

Implant Specifications and Location Options

Implant Options	Implant Location			
	Submuscular (total)	Submuscular (partial)	Retromammary	Retromammary Subfascial
Shell				
Smooth	++++	++++	++	+++
Textured	++++	++++	++++	++++
Filler				
Saline	++++	++++	++	+++
Silicone gel	++++	++++	++++	++++
Shape				
Round	++++	++++	++++	++++
Anatomic	++++	++++	++++	++++

Degree of effectiveness indicated by number of pluses.

Implant Placement

Incisions

Several incision sites are available to the surgeon, depending on the procedure and patient characteristics:

- Axillary
- Periareolar
- Transareolar
- Inframammary
- Umbilical

My preferred incision in a patient with an established fold is the inframammary incision, which I will place below the preexisting crease; the distance below depends on the dimensions of the selected implant. In a patient with no fold, I prefer the axillary approach and will place the incision within the distalmost axillary crease. I make the periareolar incision only in combination with mastopexy. I have no personal experience with the umbilical or transareolar approaches bisecting the nipple. In general, I prefer not to involve the breast tissues, specifically the ducts, in performing breast augmentation.

Choosing the Best Option: Breast Augmentation Approaches					
Breast Characteristics	Incision				
	Axillary	Periareolar	Transareolar	Inframammary	Umbilical
Mammary Fold					
Well-defined					
Undefined					
Areola					
Size					
Wide					
Narrow					
Color					
Dark					
Light					
Patient Preference					

Location

The options for implant placement include retromammary, retromammary subfas-
sial, partial subpectoral, and complete submuscular. I reserve complete submuscu-
lar implant coverage for breast reconstruction with implants. For breast augmenta-

tion, I choose between the retromammary and partial subpectoral position based on the shape and thickness of the breast. However, the relationship of the skin to the underlying parenchyma also plays a role in this decision, as would minimal ptosis. In patients with minimal ptosis whose breasts are amenable to correction through implant placement, I will opt for retromammary placement, provided the tissues are thick enough. If they are not thick enough, I choose submuscular placement with the dual plane approach.

All things being equal, I prefer retromammary placement of the implant above or below the pectoral fascia. In this position the breasts have a more natural appearance, and the distortion seen with pectoral contractions is eliminated. The main advantage to retromuscular placement is the extra thickness afforded by the pectoralis muscle, which in thinner women will provide more adequate implant coverage, lessening the potential for visible, palpable rippling, particularly with saline implants. In women with less than 2 cm of breast thickness, especially superiorly and medially, I prefer partial submuscular placement of the implant, whether saline or silicone gel. I will only place saline-filled implants over the muscle if the breast thickness is 3 cm or more.

Recently several reports have shown the benefits of subfascial placement of breast implants. The pocket is made deep to the breast tissue, over the pectoralis major muscle, but including the pectoral fascia. Proponents believe that inclusion of this thin fascial layer will add further protection or tissue volume around the implant. However, this fascia can be very thin, adding very little volume. It would be far better to include the entire 5 to 10 mm thickness of the pectoralis major muscle if deemed necessary rather than the fascia.

Tissue Characteristics and Implant Location Options

Tissue Characteristics	Implant Location			
	Submuscular (total)	Submuscular (partial)	Retromammary	Retromammary Subfascial
Skin				
Normal elasticity				
Nonelastic stretched				
Breast Tissue Thickness				
<2 cm				
>2 cm				
Ptosis				
Ptotic				
Nonptotic				

Conclusion

I always counsel any woman seeking breast augmentation that implants are not permanent, will eventually leak, and will have to be changed; that breast augmentation is not maintenance free; that regular follow-up examinations are mandatory; and that her first pair of implants will not be the last. In terms of size, I find that most patients come in after having talked to friends, researched on the Internet, and made up their minds as to their desired implant volume or bra size. It takes a lot of patience and skill to discuss these issues with patients and to reconcile their desires with the reality of their chest dimensions and tissue characteristics. I emphasize that inappropriately large implants, especially those filled with saline, will lead to serious long-term complications. I explain to them that a dimension-based implant selection will match their breast size to the most appropriate implant, and the choice of access incision and implant placement, subpectoral or retromammary, is also made to match their physique and tissue characteristics.

Breast Reduction

The goals of breast reduction are twofold: aesthetic and functional. Most women seeking breast reduction have symptoms related to the large size of the breast and the impact that breast weight has on their lifestyle, and on their ability to work and exercise. Symptoms include pain and discomfort in the neck, back, and shoulders; shoulder grooving, excessive sweating, or frank intertrigo in the inframammary fold. The ideal procedure should not only enhance the form of the breast but also relieve the patient of these symptoms. A sufficient volume of breast tissue must be resected to achieve these ends. Postoperative dissatisfaction with breast reduction is not limited to scars and shape—far too often the patient complains that her breasts were not sufficiently reduced in weight or volume to relieve the symptoms. Although our priority is the aesthetic result of the reduction, surgeons must not lose sight of the patient's goal: relief of symptoms as well as aesthetic improvement.

Aesthetic goals are to reduce and reshape the breast with the nipple-areola complex in the appropriate position through minimal scars and with minimal risk of nipple-areolar loss, delayed healing, or wound disruption. By far the most common cause of dissatisfaction and even litigation after breast reduction is scarring. For years breast reduction procedures, although resulting in volume reduction, resulted in poor breast shape, nonprojecting square or wide breasts, and extensive scarring. More recently, greater emphasis has been placed on improvement and maintenance of shape with minimization of scars.

This young woman, who underwent an inferior pedicle Wise pattern breast reduction elsewhere, was seen for evaluation of scars and shape improvement. She demonstrates wide, nonprojecting breasts that have bottomed out, and extensive inframammary scarring that extends beyond the breast, across the midline, and past the anterior axillary fold.

The typical long-term result is shown after a central pedicle Wise pattern breast reduction. Despite the pleasing appearance of the breasts, projection is moderate and bottoming out is noted, especially on the left side.

The typical result after breast reduction using the superior pedicle vertical technique demonstrates projecting breasts.

Side-by-side comparison emphasizes the difference in shape and projection.

A number of operative procedures are available for breast reduction with a variety of pedicles to maintain the nipple and areola, a variety of techniques to shape the breast, and varying lengths of incisions. There is a tendency to refer to breast operations by the resulting scar, such as *periareolar*, *vertical*, and *inverted-T*. These terms should refer only to the scar and reflect the pattern of skin excision. Different pedicles and shaping techniques can be performed through each of these incisions. The appropriate way to refer to a particular technique for breast reduction should include the pedicle, the breast-shaping method, and the resultant scar.

All breast reductions—regardless of pedicle selection, scar placement, or scar length—entail four steps:

- Incisions for access
- Parenchymal resection
- Breast reshaping
- Management of excess skin

With the Wise pattern, all steps are performed through the preoperative markings, affording the best exposure and the option for limitless skin excision. On the other hand, the periareolar approach offers very limited exposure and skin excision. The short-scar options fall in between.

The short-scar superior pedicle or medial pedicle options narrow the base of the breast, increase projection, and push the nipple upward, whereas the Wise pattern central or inferior pedicle procedures widen the base, flatten the breast, and displace the nipple downward. It is not the scar or the pedicle that defines the procedure or the result. It is the tissues resected, the location in the breast where they are resected, and how the breast is reshaped that define the result.

Liposuction-Only Breast Reduction

The ultimate short-scar technique, liposuction-only breast reduction, has a role in breast reduction. Both ultrasound-assisted liposuction (UAL) and suction-assisted liposuction (SAL) have been successfully applied to reduce the volume of the breast. Liposuction has also been advocated for correction of ptosis through skin contracture. Although there is no question that liposuction will significantly alter the volume of the breast, it has minimal effects in terms of reshaping and enhancing projection or the appearance of the breast. However, it is relatively simple, fast, and safe with little, if any, risk of nipple-areolar sensory changes or loss. It is best for individuals who may not be able to tolerate a 3-hour breast reduction procedure and are not concerned about improving breast shape. A small number of younger women with large, nonptotic breasts and normal skin elasticity are also good candidates for this technique.

Liposuction perhaps enjoys a wider role as an adjunct to breast reduction, especially in recontouring the lateral part of the breast and the anterior axillary fold area.

SAL has proved safe and efficacious for breast reduction, and fears of tumor dissemination have proved to be unfounded when preoperative mammography has been performed. However, concern regarding the safety of UAL within the female breast is as yet unresolved.

Pedicles

A variety of pedicles have been described for breast reduction. Although all are essentially safe and based on sound anatomic knowledge, some are more popular than others. Each pedicle has its own advantages, disadvantages, and special indications. Each surgeon has his or her preferred pedicle based on training and experience. Pedicle selection is based on the technique and size of the breast. The most devastating local complication of breast reduction is nipple-areolar loss. Familiarity with a pedicle and its limitations will minimize such risks. Compromised circulation, as in a heavy smoker, increases the risk of nipple-areolar loss, regardless of the pedicle chosen.

The nipple-areola complex has an extensive blood supply radiating centrally from the periphery. The blood supply is based on the perforators of the internal mammary artery through the pectoralis major muscle, the perforators based on the intercostal vessels, laterally and medially, and the external mammary artery. A variety of pedicles are based on these vessels.

Sensory innervation of the nipple-areola complex after breast reduction depends not only on the pedicle selected but more so on the degree of nipple displacement and the volume of resection. With very large breasts, the incidence of postreduction changes in nipple-areolar sensitivity is high regardless of the pedicle chosen. Breast-feeding after breast reduction is more dependent on pedicle selection.

Pedicle Options

Pedicle options include the following:

- Inferior
- Central
- Medial
- Superior
- Lateral, including septum-based
- Combinations
- Free nipple graft

The central and inferior pedicles have been the most popular, especially in North America. These pedicles are safe and can be applied equally to minimally, moderately, and massively enlarged breasts. The vascular basis of these pedicles is the musculocutaneous perforating branches of the internal mammary artery through the pectoralis major muscle and intercostal perforating branches through the muscle. These pedicles are reliable; however, the need to preserve and maintain central and lower breast tissue may lead to postoperative bottoming out. Breast-feeding after reduction with the central and inferior pedicles is usually possible, and preservation of nipple-areolar sensitivity with small to moderate reductions is possible.

The medial pedicle has gained favor as a safe alternative to the superior pedicle for short-scar vertical reductions. The pedicle is based on medial perforating branches of the internal mammary artery through the pectoralis major muscle and intercostal perforating branches. It is a reliable pedicle for minimally, moderately, and even massively enlarged breasts, allowing easier elevation and inset of the nipple-areola than the superior pedicle. The medial pedicle allows resection of central and lower breast tissue, which contributes to the minimization of bottoming out. Breast-feeding is possible after reduction with the medial pedicle, and preservation of nipple-areolar sensitivity is also possible.

The superior pedicle, popularized with the Lassus and Lejour vertical techniques, is based on superior perforating branches of the internal mammary artery (most notably the second perforating branch) through the pectoralis major muscle, perforating branches of the intercostal arteries, and branches of the external mammary artery. It is a safe and reliable pedicle best suited for minimally and moderately enlarged breasts where nipple-areolar elevation and inset are relatively straightforward. For a

massively enlarged breast, the nipple and areola are carried on a long dermal extension. Nipple-areolar elevation and inset are not always easy and may require careful liposuction of the pedicle base to inset the nipple-areolar complex. The superior pedicle allows resection of the central and lower breast tissue, eliminating lower breast volume, which contributes to bottoming out. It is less likely that the patient will be able to breast-feed after the superior pedicle technique, especially with a dermal extension, than other techniques. Nipple-areolar sensory preservation is possible.

The lateral pedicle based on the external mammary artery enjoys the same advantages as the medial pedicle, but not equal popularity. Occasionally, in an extremely ptotic breast, I will combine a superior central and even inferior pedicle to ensure nipple-areolar safety. For truly gigantic breasts, extremely ptotic breasts, and in women who are heavy smokers, the free nipple graft is a safe alternative. Although hypopigmentation is a common problem, it would be preferable to total nipple-areolar loss. Breast-feeding is possible after the lateral pedicle technique, and nipple-areolar sensation is preserved. Obviously, with the free nipple graft there is little, if any, chance of the ability to breast-feed or preservation of nipple-areolar sensation. The septum-based pedicle is basically a modification of this lateral pedicle.

Breast-Shaping Techniques

The original Wise pattern technique, which was the mainstay of breast reduction for many years, especially in North America, relied on the skin brassiere to maintain shape. This inevitably led to the all too familiar wide, nonprojecting, bottomed out appearance. We no longer rely on a skin brassiere to shape or maintain the shape of the breast. Our priority now is to reduce the breast parenchyma, shape the new breast tissue, and then manage the excess skin. I refer to this as *shape and drape*—that is, shape the breast, drape the skin, and then manage the skin excess. Not only have these recent advances improved breast shape, they have also yielded longer-lasting results.

Breast-shaping techniques range from the internal mesh application advocated by Sampaio Góes to a variety of parenchymal incision and suturing techniques, and to the pectoral sling technique of Daniel, as popularized by Graf and Biggs.

My personal preference is the vertical scar superior pedicle technique described by Lassus. Resection of the central and lower breast tissue removes the breast mass, and the breast shaping is performed through suturing of the medial and lateral pillars. This, in fact, is the basis of the breast shaping with the medial and lateral pedicle short-scar techniques. The Daniel technique involves isolation of an inferiorly based dermal-glandular flap of breast tissue, which is mobilized, passed through a pectoralis muscle loop, and sutured onto the chest wall. The loop provides stability for this flap, which improves breast projection. The breast is further shaped through suturing of medial and lateral pillars. The illustrations show the Daniel method, as popularized by Graf and Biggs.

Skin

The most important factor in limiting incision length and scars in breast reduction is not size or even nipple position; I believe it is skin quality and quantity. Short scars and optimal breast shape are compatible and limited only by skin quality, skin quantity, pedicle safety, and surgical experience. The inverted-T is still the standard in the United States, and without question allows maximal skin removal and maximum exposure to the breast parenchyma for shaping procedures. I believe its role should be limited to skin excision only, and not used for breast shaping. The length and placement of the scar in reduction and mastopexy should reflect the surgeon's choice for management of the excess skin. A number of the short-scar techniques, especially those leaving only a periareolar scar, rely heavily on skin contraction as a way of dealing with skin excess.

The ideal approach to breast reduction is to resect the excess volume, then shape the breast, drape the skin, and finally deal with the redundant or excess skin. This concept of shape and drape is best demonstrated in this woman, who underwent a 700 g reduction through a vertical incision with a superior pedicle. The redundant or excess breast skin is clearly shown. Options for dealing with this include excision and closure with a purse-string suture, a short horizontal T, or a J or L excision. Even in such a large reduction, there is no need for a long horizontal component.

As stated previously, size is not the issue; skin redundancy and skin elasticity, mandating skin resection, are the ultimate arbiters of scar length. Although these three women have breasts of differing sizes, they all have normal skin elasticity, a full breast envelope, and skin that is firmly adherent to the underlying breast. It is not possible to pinch the skin away from the breast parenchyma of any of the three women shown above. Therefore they are all good candidates for breast reduction through limited scars. They do not have skin laxity or an excessive amount of skin that cannot be managed through limited scars.

In contrast, these three women, who also have different-sized breasts, are not the best candidates for short-scar techniques because they demonstrate poor skin elasticity, partially filled breast envelopes, and skin that is loosely adherent or nonadherent to the underlying breast tissue. The breast skin of any of these women can easily be pulled away from the parenchyma by gentle pinching. In these women longer scars will be needed, because they have poor-quality skin that will not redrape or contract and must be resected.

The incision options for dealing with excess skin include the following:

- Periareolar
- Vertical
- Small T
- J or L
- Full-length inverted-T

As we progress down this list, we are able to remove increasingly larger amounts of skin. The higher we remain on the list, the more we rely on skin redraping and contraction, two options not available with stretched, inelastic skin.

My concept of breast skin excision is three-dimensional: *unidimensional* refers to periareolar skin removal; *bidimensional* includes a periareolar and a vertical component; and *tridimensional* includes a periareolar, vertical, and horizontal component. The horizontal component may include a short T, a J or L, or the long horizontal T.

Periareolar scar—unidimensional skin removal to the level of the areola

Periareolar and vertical incision; bidimensional skin removal adds vertical skin take-out to the periareolar component, leaving the typical vertical scar

J or L horizontal component added to the vertical and periareolar incision; tridimensional skin removal provides the option of skin excision along the lateral side of the inframammary fold

The short horizontal-T tridimensional skin incision adds a third component of skin excision for a short distance on each side of the meridian of the breast

The longer horizontal incision allows maximal skin resection

Conclusion

There has been considerable progress in breast reduction over the past two decades. Through the efforts of our colleagues in Europe and South America, short-scar techniques are slowly being accepted and adopted in North America. The concept of reducing and reshaping the breast through minimal scars is sound and here to stay. A variety of reliable pedicles are available to ensure nipple-areolar survival, and a variety of suturing and shaping techniques are available to produce the desired breast shape and projection. Although it is not essential, desirable, or even possible for a surgeon to be intimately familiar with all of these options, it is important that the surgeon be familiar with two or three approaches. In the final analysis, we will each pick the pedicle-shaping technique and incisions with which we are familiar and that in our hands produce consistently good results, with minimal morbidity and minimal scarring acceptable to our patients while meeting their expectations.

The role of the quality and amount of excess skin in defining the length and placement of scars in reduction and mastopexy has been discussed. Not only skin quality and skin excess, but the relationship of the skin envelope to the breast, together with the quality and type of breast tissue (fat versus fibrous tissue), should be taken into account when choosing the procedure. These same parameters also determine the quality and longevity of the result.

The following three women had breast reductions of varying amounts: 300, 500, and 1000 g per breast. A superior pedicle technique was used with a vertical scar. All demonstrate size reduction, shape enhancement, and minimal scars.

Breast reduction: 300 g per breast

Breast reduction: 500 g per breast

Breast reduction: 1000 g per breast

Choosing the Best Option: Breast Reduction Approaches

Breast Characteristics	Skin Excision Pattern and Final Scar				
	Periareolar	Vertical	Short Horizontal T	J or L	Longer Horizontal T

Firm and fibrous					
Soft and fatty					
Skin-Parenchyma Relationship					
Firmly adherent					
Loosely adherent					

Mastopexy

Mastopexy is not only one of the most difficult breast procedures, but perhaps one of the more challenging of all aesthetic procedures. Patients have high expectations, yet the quality of their tissues, gravity, and aging all conspire against the patient and surgeon alike. A variety of procedures are available, with or without implants, to lift, reshape, and resize the droopy breast. It is essential to thoroughly evaluate the patient and her breasts before selecting the appropriate technique.

In my practice the quality of the tissues not only guides me in selecting the appropriate procedure for each patient, but also enables me to predict the quality of the result so that I can better explain and demonstrate to the patient the anticipated result and how long it will last.

Most patients seeking mastopexy want fuller, perkier, lifted breasts. Before examining the breasts, I try to establish whether the patient is happy with her present breast volume and simply looking for a breast lift or whether she is seeking both volume

enhancement and a lift. If possible, it is best to undertake a mastopexy after the woman has completed her family rather than between children.

Evaluation of the breasts includes grading of the ptosis. Currently the two classifications available are those of Laldardie and Regnault, glandular or cutaneous. The Laldardie classification includes grades I through IV, based on nipple-areolar position. Regnault's classification, described in 1976, is more complicated but takes more into account. Regnault's classification defines the different degrees of breast ptosis and facilitates evaluating the problem and planning the operation.

Minor ptosis: Nipple at level of inframammary fold

Moderate ptosis: Nipple below inframammary fold but above lower breast contour

Major ptosis: Nipple at lower breast contour; breast below inframammary fold

Glandular ptosis: Nipple above inframammary fold/breast descended below fold

Pseudoptosis: Nipple higher above inframammary fold; gland hypoplastic with some breast descended below fold

Although such classifications are useful, not all women can be classified into each of these categories. In addition, these classifications do not take into account the quality and quantity of excess skin or the relationship of the skin to the underlying gland. My preference is to evaluate the skin envelope and contents, the relationship of the skin to the gland, and finally the nipple position.

Evaluation of the Ptotic Breast

To fully evaluate a patient's ptotic breasts, the surgeon must consider the following:

- Skin
- Gland
- Skin-gland relationship
- Nipple position

In the skin I look for loss of elasticity, as evidenced by striae, dermal thickness, and skin recoil. I also make a mental note of the excess skin to be resected. The breast tissue is evaluated for shape, volume, and consistency: Is the breast mostly fibrous, fatty, or a combination of the two? In terms of the skin-gland relationship, I assess whether the envelope is full or empty. Is the skin adherent to the underlying tissues,

or hanging loosely around it? Skin quality and the skin-gland relationship are the key factors in determining the appropriate procedure and the quality and longevity of the result. Finally, I assess the displacement of the nipples and the degree of nipple elevation that will be required.

Patient Profiles

This young woman has full, large breasts. The skin has normal elasticity and recoil, the gland is firm and fibrous, the envelope is full, tight, and firmly adherent to the parenchyma. The skin cannot be pinched away from the breast tissue. Her nipples are displaced moderately. A good result is anticipated in this woman regardless of technique, because all of her tissue characteristics are favorable and she has more than adequate breast volume.

This young woman has partially atrophic breasts; her skin has maintained some elasticity and recoil. Her gland is soft and fibrofatty. Her skin envelope is half-full, loose, and lightly adherent to the parenchyma, and the skin can be pinched away from the breast tissue. Her nipples are moderately displaced. A good result is anticipated, but the degree of projection will depend on the technique. I would certainly consider an implant for this patient.

This middle-aged woman has deflated breasts. The skin has lost most of its elasticity and recoil, the gland is loose and fibrous, and the skin is barely adherent to the parenchyma. The skin can be pinched away for 2 or 3 cm from the breast tissue. Her nipples are moderately displaced. A reasonably good result can be anticipated, but given the quality of her skin, it will not be a long-lasting result, and the patient should be warned about the possible need for early secondary procedures. An implant should also be considered.

This middle-aged woman has deflated, atrophic, and asymmetrical breasts. Skin elasticity and recoil are minimal. The gland is soft and fibrous, and the skin envelope is empty and barely adherent to the underlying parenchyma. The skin can easily be pinched away several centimeters from the breast tissue. An average result may be anticipated; however, the patient should be warned that it will not be a long-lasting result and that a revision may be required sooner rather than later.

Goals of Mastopexy

The goals of mastopexy include the following:

- Restoration of shape
- Restoration of volume
- Restoration of nipple-areolar position

Restoration of Shape

The ideal result after mastopexy is a projecting breast with the nipple and areola at the point of maximal breast projection. There should be breast volume above and below the nipple-areola complex, more below than above. The breast should also be appropriately positioned on the chest wall.

Restoration of Volume

Many women seeking mastopexy have postpartum involution and a deflated appearance. Although they are candidates for volume replacement with an implant, they are surprised when the recommendation is made, because they feel that they have adequate breast volume. During the initial evaluation, I tighten the breast skin with my fingers to bring the nipple-areola complex to the appropriate position; this demonstrates to the patient the anticipated breast volume, without an implant postoperatively. While holding her skin, I ask her to look down at her breast and into a mirror to preview this breast volume. Most patients who thought that they had adequate breast volume in the ptotic stage are surprised that the breasts will look smaller once the ptosis has been corrected. I also explain to patients who require an implant that their results will be better in terms of projection and in all likelihood will last longer with an implant. There is a small group of women whose minor degree of ptosis may be corrected with an implant without any skin envelope adjustment.

Restoration of Nipple-Areolar Position

Restoration of nipple-areolar position is an integral part of the mastopexy, and care should be taken to preserve the blood supply to and venous drainage from the nipple-areola complex, especially if the mastopexy is combined with an implant.

Skin Removal and Mastopexy

As with a breast reduction, skin excision is planned according to the tridimensional approach: periareolar, vertical, and horizontal planes. The skin incision is designed to allow sufficient access to the breast tissue for reshaping, placement of an implant, and removal of excess skin. It should be noted that inelastic, stretched skin with striae, and a skin envelope that is poorly adherent to the underlying breast parenchyma will not redistribute or contract and must be excised.

Establishing Surgical Priorities

During the patient evaluation, I identify the predominating needs of the breast. If volume deficiency is predominant, volume replacement is performed first and then skin excision. If the predominant factor is skin excess rather than volume, the breast is shaped and the excess skin resected. If volume deficiency and skin excess are equal determining factors, volume adjustment is performed first, followed by skin removal.

Skin Removal and Incision Placement

Similar to excisions for reduction mammoplasty, skin removal for mastopexy is planned to permit circumareolar, vertical, and, when necessary, horizontal excisions and remodeling of the breast to a more natural, uplifted, conical shape. This skin removal should also allow repositioning of the nipple and areola and, if ptosis recurs, additional corrections through the initial incisions. The incisions and skin excisions are planned on a continuum from periareolar to circumareolar to vertical scars and then to horizontal scars. With this approach, additional breast tissue can be excised later.

When the nipple-areola complex is low, requiring only a small degree of elevation of 1 to 2 cm, an upper periareolar crescentic ellipse can be excised to elevate it. An augmentation mammoplasty may be done through this incision, if needed, to enhance breast volume to produce an elevated nipple-areolar appearance.

This upper periareolar ellipse can be rotated when specific lateral or medial positioning of the nipple-areola complex is necessary to move it to a more aesthetic position on the breast.

A circumareolar skin excision with periareolar purse-string closure tightens the skin minimally without elevating the areola. It is effective for patients with tubular breasts with protuberant areolae and for patients with very large areolae and pseudoptosis who are to have augmentation mammoplasty. Removal of breast skin leaves only a central circular scar. The scar, however, tends to widen, and the nipple position is minimally elevated. It can also result in unnatural central breast flatness and loss of attractive central projection; however, an implant can minimize this flatness. Alternatively, breast shaping and internal mesh support, as advocated by Sampaio Góes, can enhance shape and projection. A permanent circular suture in the skin periphery, the round block technique, reduces final skin tension and produces a finer scar; this approach extends the application of this technique to some patients with moderate ptosis.

In patients with glandular and minor ptosis, the circumareolar excision with a short vertical ellipse tightens the skin and elevates the nipple-areola complex. Care must be taken to avoid excessive tightness below the areola. This incision can be shortened, because the vertical component contributes primarily to close the defect from the transposed nipple-areola complex. The vertical scar tends to shorten in the post-operative period with scar contraction.

For moderate ptosis the circumareolar excision with a vertical and occasionally a short horizontal ellipse, J or L excision, produces a short inframammary scar and tightens the breast while shortening the inframammary distance. This approach is best only when there is excess skin after vertical mammoplasty that will not redrape, contract, and must be excised. Rather than the short horizontal, J or L excision, I prefer to take up the skin excess through a purse-string suture.

For patients with major ptosis and excessive amounts of inelastic skin, who need maximal breast elevation, a vertical and horizontal excision provides effective breast elevation, even though this approach produces a longer inframammary scar. However, I make every effort to avoid the horizontal component if possible.

Mastopexy Augmentation

Combining mastopexy with augmentation is even more challenging than mastopexy alone. The goals of the two procedures are diametrically opposed. Mastopexy tightens and lifts the breast, whereas an implant stretches and expands the tissues and often displaces the breast downward. Opinions differ as to whether this operation should be staged. My preference has always been a one-stage procedure in which the

implant is placed first, and then the patient is marked for the mastopexy on the table during the operation. As with reduction and mastopexy the quality of the tissues, including the skin, will guide me in selection of technique and the anticipated result.

Conclusion

Mastopexy is a challenging procedure; the results are not permanent, and early re-operation may be required to produce the optimal result. A compromise must be struck between the patient’s expectations and the realities of her tissue characteristics. Careful evaluation of the breast volume, skin, and tissue characteristics is an essential prerequisite for operative planning. The patient should be counseled about the limitations and longevity of these procedures. Technique selection and skin excision patterns reflect the same principles as those discussed for breast reduction. If an augmentation is planned, the breast volume should be adjusted first and then the skin envelope.

CHAPTER 61

Choosing the Right Breast Implant

DENNIS C. HAMMOND

The original design for a breast implant was inspired by the observation that the saline in a half-filled intravenous bag assumed a breastlike shape. From there the first silicone gel breast implant was created, used, and subsequently reported by Cronin and Gerow in 1963. Ever since this original description, attempts have been made to engineer a better implant to improve the performance of these devices. As a result, a wide variety of different types of implants are currently available for use in aesthetic and reconstructive surgery of the breast. Despite the seeming complexity associated with these many different types, there are only three design variables that describe nearly every one of these devices: mandril shape, shell characteristics, and filling material. Understanding how these three variables mix and match allows the surgeon to better understand how these implants interact with the patient's soft tissue to produce the desired breast size and shape.

Construction

Mandril Shape

To understand how the shape of an implant can affect the subsequent shape of the breast, it is helpful to understand how an implant is made.

Courtesy Mentor Corporation

A solid form, or *mandril*, is attached to a dipping rod to determine the three-dimensional shape of the outer shell of the implant. The surface of the mandril is coated with silicone, either by dipping the mandril into a vat of liquid silicone or spraying a fine mist of liquid silicone onto the mandril. Repeated applications or dips of silicone, followed by short drying intervals, ultimately result in a thin layer of silicone rubber coating the mandril.

Courtesy Mentor Corporation

Once the shell has dried completely, the dipping rod is unscrewed from the mandril and a circular cut is made around the dipping rod attachment site. Using this as an entry point, the elastic shell is pulled off by stretching it around the edges of the mandril (*left* and *center*). Thus the basic shape of the shell is determined by the mandril that made the implant. The appearance of the silicone shell is shown immediately after removal from the mandril. The hole in the shell, created by cutting it free from around the dipping rod, has yet to be patched (*right*).

Next, the defect in the shell is patched with a separate sheet of silicone sheeting to finish the process and prepare the implant envelope for subsequent filling with silicone gel.

Courtesy Mentor Corporation

Round Implants

For the first 30 years of implant use, the predominant shape incorporated into the design of a breast implant was classified as round. This description is actually a minor misnomer: a “round” implant actually has a shaped aspect to its design. These

implants are symmetrical in the horizontal and vertical dimensions; however, the projection tends to be less than the width or height of the device. Thus a round implant is asymmetrically constructed and is therefore shaped. This minor nuance becomes important when considering the behavior of breast implants in situ with regard to how the ultimate three-dimensional shape of the breast is created.

Anatomically Shaped Implants

What has been traditionally called an “anatomically shaped” implant is an implant shell that takes the shaped concept a step further, with the dimensions of the implant being asymmetrically designed in the horizontal, vertical, and sagittal (projection) dimensions. Here, the implant height is typically longer than the width, and the projection of the device gradually increases from the apex of the device down to the lower third of the implant. As a result, these devices demonstrate a teardrop shape designed to mimic the contour of a normal breast in the upright position.

Texture

The original silicone gel implants were constructed with a smooth surface. However, in the early 1970s it was discovered that coating an implant with a layer of polyurethane foam resulted in a dramatic reduction in the rate of capsular contracture. This resulted in part from a low-grade inflammatory giant cell response to the polyurethane, creating an ultrathin, pliable, and highly convoluted capsule.

These images depict the polyurethane foam being pulled off a round gel implant, demonstrating the thickness of the foam as well as the porous nature of the material. The scanning electron micrograph image shows the polyurethane foam layer. Note the interconnecting lattice network with the variation in the size of the pores.

Unfortunately, over 10 to 15 years, the foam completely degraded away, resulting in cases of late capsular contracture around the now smooth-walled silicone gel implant. In an attempt to mimic the effect of the polyurethane foam, texturing of the surface of silicone gel implants was developed. To date, two basic textures are used in the vast majority of silicone and saline implants: Biocell and Siltex.

Biocell

The Biocell surface (Allergan) is created by coating a tacky implant shell with salt granules and letting the outer implant shell harden. By subsequently washing away the salt granules, an open pore lattice network is created that leaves an aggressive texture on the surface of the implant. The stereoscopic view (*left*) demonstrates the Biocell textured surface with its variably sized, squarish pores left after dissolution of the salt granules from the surface. The scanning electron micrograph view (*right*) demonstrates the relationship of the pores to the underlying elastomer shell.

This texture can actually interact with the capsule that develops in a favorable manner by causing the collagen fibrils of the capsule to become intertwined with the texture of the shell. Such ingrowth occurs much more commonly with tissue expanders than with implants, because the outward force of the inflated expander tends to drive the textured surface into the capsule. By interlocking the capsule with the textured surface, two events occur. First, the device becomes immobile, a feature that is particularly useful when using anatomically shaped devices that must maintain the proper orientation. Second, many surgeons think that the textured surface reduces the rate of capsular contracture, similar to that with polyurethane foam. This latter finding is somewhat controversial; several studies have failed to note a reduction in the rate of capsular contracture associated with the use of textured implants.

Siltex

The Siltex surface (Mentor) is created by pressing a thin layer of polyurethane foam into a thin tacky sheet of silicone. The sheet is then allowed to cure, and then is cut and attached to an otherwise smooth implant shell. The scanning electron micrograph of the Siltex textured surface (*left*) demonstrates the imprint of the polyurethane foam sheet left on the shell. A similar view is shown (*right*) that highlights the relationship of the texture to the remainder of the thickness of the shell.

This is a less-aggressive texture that does not demonstrate tissue ingrowth. Despite this finding, rotation of an anatomically shaped Siltex textured implant is very uncommon, primarily because the rough texture exerts a “fingerprint” effect on the surface of the implant, producing enough friction between the device and the capsule to effectively hold the implant in position. As with the Biocell device, many studies have suggested a reduction in the rate of capsular contracture when this texture is used, although again, the point remains somewhat controversial.

Fill

Although several alternative filling materials, such as hydrocolloid gel and peanut oil, have been proposed over the years, the only two that have stood the test of time have been saline and silicone gel. Saline has the obvious advantage of being readily available, entirely physiologic, and inert, which affords a particular advantage when a saline implant ruptures, because the saline is simply absorbed and excreted without sequelae. The surgeon can fill the device during surgery; thus differential implant filling techniques can be employed to manage asymmetries in a very controlled fashion. The disadvantage of saline relates to the feel of the implant that results, because the low cohesivity of saline results in a fluidlike water-balloon effect on the implant that can be seen and/or felt in thin patients.

However, silicone gel has much more inherent cohesivity, producing a softer, more natural feel to the implant. The appearance of the less cohesive memory gel present in standard textured and smooth round silicone gel implants is shown above. The gel is less extensively cross-linked during curing, leading to a looser consistency to the gel (*left*). The gel can also be structurally cross-linked to a greater degree to create a firmer gel that is used to support the shell in anatomically shaped implants. The appearance of the gel from an anatomically shaped cohesive gel device is shown (*right*). Because of a greater degree of cross-linking of the silicone molecules, it has a firmer consistency, which translates to better support for the anatomically constructed shell. However, because these implants come prefilled, the volumes are limited to a defined schedule of choices. If the implant ruptures, the gel remains in the periimplant space, and an operative procedure must be performed to remove the implant material.

Design

Implant Shape

Taking the three design variables into consideration—mandril shape, shell characteristics, and filling material—it is possible to combine them into a host of possible implant designs. However, the predominant variable is the shape of the device. To this end, two basic groups of implants are commonly used today: round or anatomically shaped.

Round Implants

All round implants have a horizontal and vertical dimension that is symmetrical. However, several different types of round implants are available that differ in projection. Most manufacturers offer round implants with three different projections for a given volume. These are generally named using a system that designates them as having a low, mid, and high projection or profile.

Anteroposterior and lateral views are shown of a series of moderate, moderate plus, and high profile implants, all with a 325 cc fill volume. It is important to realize that for these devices with volume as the fixed variable, as the projection of the implant increases, the base width of the device decreases. This has implications for how these implants are used in specific patients. For instance, a patient with a tight skin envelope and severe macromastia will not be able to tolerate a high projection or high profile implant without creating tension at the apex of the device, resulting in a rounding out of the periphery of the implant and possibly creating a prominent, rounded contour at the breast periphery. In such cases a moderate profile implant is a better option, because it will fit beneath the skin envelope without crowding the space, creating a more comfortable relationship between the implant and the soft tissue and a more aesthetic and natural result. Conversely, in a patient with a very loose skin envelope, a low profile implant could nicely augment the base of the breast but not adequately fill out the apex of the breast mound, creating an odd appearance where the peripheral contours of the breast were filled out, with the apex of the breast actually hanging off the front. In these instances, a high profile implant would be a better choice, because it would more evenly fill out the loose and redundant skin envelope.

Beyond issues related to projection, what the implant is filled with can dramatically affect its performance. Because of their relatively low level of cohesivity, saline-filled implants must be filled to a greater degree than silicone gel implants to perform safely;

an under-filled saline implant cannot support the upper pole of the device when it is placed upright, resulting in collapse of the upper pole and wrinkling of the shell. Such wrinkling results in sharp stress points in the shell that can weaken over time, leading to rupture. For this reason, many surgeons slightly overfill saline implants to prevent wrinkling and lengthen the life of the implant. One disadvantage of this overfill strategy is the more rounded contour of the overfilled round device. In thinner patients, this rounded contour can distort the breast, creating an artificial, augmented appearance. Filling the round implant with silicone gel is more easily tolerated by the round implant shell. Here an underfill strategy can be used, because the wrinkles that form are much softer and place less stress on the implant shell. The wrinkles are also less likely to become visible through the skin envelope. This, together with the overall softer feel of silicone gel-filled implants, makes these the implant preferred by many surgeons.

Anatomic Implants: Design Variations

Shortly after the introduction of the silicone gel implant for breast augmentation, it became clear to early practitioners that an anatomically shaped implant held at least a theoretical advantage in creating a pleasing breast shape.

To this end, a shaped silicone implant was introduced that had five Dacron patches attached to the back that held the implant in position and prevented rotation because they stimulated intense tissue ingrowth into the patches. Anteroposterior and lateral views are shown of the original shaped silicone gel implant from the late 1960s. (Note the five Dacron patches attached to the back of the device.) From an engineering standpoint, this was a sound implant design, and the merging of a shaped

device with a means to hold the implant in the proper anatomic position is a valid concept that applies to the use of anatomically shaped devices even today. However, as can be seen in the example on p. 2213, severe capsular contracture was quite common with this particular early implant design, and the implant fell into disfavor.

Eventually a polyurethane foam-coated device with an anatomic shape called the Replicon implant, developed by Surgitek, was introduced that again merged a textured surface that stimulated tissue ingrowth with an asymmetrical anatomically shaped implant. This device was considered by many to be one of the most effective breast implants ever designed. The device allowed better control of the shape of the breast and, what is perhaps more important, remained soft over time, leading to one of the lowest rates of capsular contracture ever reported. The biochemical effect of the slow degradation of the polyurethane foam was somehow inhibitory to contracture of the capsule. Unfortunately, the safety of this foam degradation process was called into question in the early 1990s, because the byproducts of polyurethane foam breakdown were thought by some to have carcinogenic potential. These concerns were eventually dismissed as unfounded, but these types of devices were eventually removed from the market and have not yet become available again in the United States.

With the development of textured silicone surfaces, once again there was an opportunity to apply an implant fixation method along with the anatomic concept for breast implants, and over the years several different anatomic designs for both silicone and saline have been introduced, as demonstrated in the lateral views shown next.

The Biocell (363 Allergan; Allergan, Inc., Irvine, CA) (*left*) and Siltex (Spectrum, Mentor) (*right*) textured short height anatomically shaped saline implants were developed for both augmentation and reconstruction.

The Biocell textured full height anatomically shaped saline implant (163 Allergan) (*left*) was thought to be better suited for reconstruction, because it could provide better upper pole fill for the breast after mastectomy. The anatomically shaped Bio-cell textured cohesive silicone gel implant (410 Allergan) (*right*) combined a variable anatomic shape with a textured surface to provide a controlled result in both augmentation and reconstruction.

A lateral view of an anatomically shaped Siltex textured cohesive silicone gel implant (Contour Profile Gel [CPG], Mentor) is shown.

This side-by-side view shows a saline-filled implant placed upright compared with an anatomically shaped cohesive gel CPG implant (Mentor). As a result of the support the cohesive gel provides to the anatomically shaped shell of the CPG, the implant holds its shape when placed upright, whereas the saline device collapses in the upper pole, leading to the possible formation of visible or palpable wrinkles.

Whatever the specific design, the concept remains the same; namely, by building an anatomic teardrop shape into the implant, a better, more aesthetic breast shape can be created through both aesthetic and reconstructive breast surgery.

Combination Implants

In an attempt to combine the advantage of saline volume adjustability with the softer feel of silicone, manufacturers have developed a series of combination devices that incorporate a dual-lumen concept. Generally, the outer lumen is constructed with a silicone gel filler and the inner lumen is filled with saline. A remote valve passes through the outer gel component to allow access to the inner saline portion.

This anatomically shaped dual-chambered device has an inner saline bladder attached to the lower pole. The fill tube enters the inner saline bladder through a valve port built into a patch on the back of the implant.

The remote port is then buried under the skin and is accessed as needed to add volume to the overall implant. This device was introduced as a combination expander-implant, because the external valve portion could be removed and a self-sealing mechanism would maintain the integrity of the device. In reconstructive cases, once the needed volume had been added, the port and tubing could be removed with the patient under local anesthesia, with the device now also functioning as the final implant.

This concept has also been explored for patients undergoing breast augmentation, with volume adjustability allowing the patient to choose the final desired size by adding saline as needed postoperatively, then eventually removing the remote port. Although this is attractive in theory, such devices occupy only a small niche applicability for the vast majority of surgeons performing aesthetic and reconstructive breast surgery.

Rationale for Anatomically Shaped Implants

The rationale for using a shaped implant has been challenged by many in plastic surgery, and the utility of a shaped device has been called into question. The counter-argument is that round implants have worked quite well over the past 40 years, and there is no need to invite the potential for implant rotation or to make a very straightforward operation more complex. This opinion is understandable, given the numerous reports that have documented the excellent aesthetic results achieved with round implants. However, these results must be interpreted in light of how these devices are actually interacting with the surrounding soft tissue to create the final three-dimensional breast shape. It is now clear that an underfilled silicone gel implant will variably fold and wrinkle, depending on the characteristics of the soft tissue cover overlying the device, as well as on the size of the pocket into which the implant is placed. In most instances, these wrinkles are masked by the overlying soft tissue and do not create a contour irregularity unless the soft tissue cover is very thin. However, when these implants are evaluated by imaging studies, the shape assumed by the implant is variably and often markedly anatomic.

325 cc smooth round moderate profile silicone gel implant

310 cc smooth round high profile saline implant filled to 350 cc

280 cc mid height low projection (321) textured cohesive gel anatomic implant

Recent data from an upright MRI scanner regarding implant shape have been obtained to evaluate the shape of the breast and the implant in the upright position. These images have documented the propensity of round implants to wrinkle and demonstrate something other than a round shape under the influence of the overlying soft tissue framework. This propensity for wrinkling can be seen with the lateral view of the 325 cc smooth round moderate profile silicone gel implant (*left*). The shell is wrinkled and the apex of the device of the device comes to a sharp point, creating a smooth takeoff from the chest wall in the upper portion of the breast.

Using upright MRI images, the relationship of the upper pole of the implant to the overlying soft tissue can also be evaluated. When the implant can change shape in the upper pole and become more angulated, deficiencies in the thickness of the soft tissue cover can be tolerated without creating upper pole distortion. It is for this reason that silicone gel implants are more versatile than saline implants, because a fixed yet underfilled round silicone gel implant can more readily fold and assume a more or less anatomic shape than a saline implant, which tends to retain a more rounded configuration when properly filled. The upright MRI scan of a 310 cc smooth round high profile saline implant is shown (p. 2217, *center*); the device has been filled to 350 cc. Note that the shell of the implant is completely filled and there are no wrinkles.

It does not take a significant leap of logic to then ask, if an implant assumes an anatomic shape in situ, why not construct it to have an anatomic shape from the beginning? Not only would the shape of the implant and therefore the breast be better controlled, but also the wrinkling and whatever deleterious effect such wrinkles would have on the shell of the implant, leading to potential weakening and rupture, would be greatly minimized. Because the anatomic implant is constructed to assume a teardrop shape, the in situ distorting forces across the top of the device are minimized and wrinkling is prevented.

This argument has been confirmed again through upright MRI evaluation of breasts augmented with cohesive gel anatomic implants, where wrinkling in the shell of the device is minimal to none. In the MRI scan of a 280 cc mid height low projection (321) textured cohesive anatomic silicone gel implant in an upright position (p. 2217, *right*), the apex of the device remains contoured to create a smooth takeoff in the upper pole of the breast. Additionally, the anatomic distribution of the gel along with the absence of wrinkling in the outer shell can be seen.

One design feature of these types of devices relates to the consistency of the gel used to fill the implant. If the gel has a greater density and is more cohesive, the magnitude of the distorting forces across the top of the device will be further minimized, and the device will effectively create a teardrop shape without wrinkling. One way to contrast the use of round versus shaped devices relates to this finding. With an underfilled round gel implant that can fold and wrinkle according to the dictates of the overlying soft tissue framework, it is the soft tissue that is shaping the implant to create the final breast contour. This is a very versatile and effective way to use a breast implant. However, with cohesive anatomic gel devices, it is most decidedly the firmer anatomic implant that is shaping the breast. In this instance there is less room for error, and each implant must be carefully measured and matched to each patient to work effectively. This is why all anatomically shaped cohesive gel implants are manufactured using a matrix strategy by which several different implant heights are merged with an equal number of different projections. Within this framework, implants of different dimensions and volumes are available for each cell of the matrix.

Anatomic Implants: Gel

Anatomically shaped cohesive gel implants are manufactured to meet the needs of a wide variety of patients. The important variables are implant height, width, projection, and volume. No matter what the variables are that define each individual implant, all are constructed with a firmer, more cross-linked gel that supports the anatomically shaped shell to better maintain the shape of the implant and resist wrinkling.

410

The first widely used anatomically shaped cohesive silicone gel implant, called the 410, was introduced in the mid-1990s (see p. 2215). Currently this device is manufactured by Allergan using a matrix structure that combines implant height and implant width with projection. The base diameter of the implant is constructed to be proportional to the overall shape of the device. Using this matrix, these devices are then named based on the variables. For example, the full height full projection implant is called the FF; the mid height mid projection implant is called the MM; and so on. Originally nine cells were included in the matrix to meet the needs of individual patients, and within each cell a wide variety of volumes were manufactured to provide versatility in implant choice. Eventually an extension to the matrix was added to provide implants with greater projection; these devices are called X for extra projection. Therefore a full height extra projection device is called an FX.

Because of concerns about the stiffness and firmer feel of these implants, an alternative matrix was developed using a slightly less firm gel, leading to a separate matrix of anatomic implants called the 410 Soft Touch. Expanding on the anatomic concept led to the development of a dual implant design called the 510. With this device, the same cohesive gel is used to fill an anatomically shaped shell, and a small insert of an even more cohesive gel is fastened inside the implant in the lower pole to resist compression and maximize projection.

Contour Profile Gel

An alternative anatomically shaped cohesive gel implant called the Contour Profile Gel (CPG), manufactured by Mentor, was introduced using the same matrix concept (see p. 2215). Here the overall resistance to compression was graded as level 3, with the standard gel of the traditional round implants called level 1, and mildly cohesive gel called level 2. Three different implant heights were offered including low, mid, and full height, labeled 1, 2, and 3, respectively. Three different projections were offered, including low, mid, and high projections again called 1, 2, and 3. The matrix system was then organized using this numbering system. Since all these devices were manufactured with type 3 cohesive gel, this whole matrix could be thought of as the 300 series. With this in mind, a mid height low projection implant is called a 321, with 2 referring to height and 1 to projection. A 323 would be a midheight full projection device. During the development of this matrix, it was realized that several of the boxes in the matrix would create implants that had limited clinical applicability. Therefore to simplify the implant selection process, these outlier boxes were removed, leaving a more refined selection of shape choices that removes the more extreme shapes, leaving behind a more clinically relevant selection of implants.

Anatomic Implants: Saline

The anatomic concept has been likewise applied to saline implants by using an anatomically shaped mandril to create the implant shell, which is then filled with saline. The advantages of this implant design include use of the anatomic concept and the ability to modify the volume of the device within a limited range of fill volumes. However, the use of saline as the fill material remains a significant drawback; as noted with round implants, saline has very limited cohesion and provides little support to the implant shell. As a result, any tendency for the implant to be under-filled results in wrinkling and loss of implant shape.

In practice, the implant actually requires a variable overfill strategy to prevent this shape change with collapse of the upper pole of the implant when it is placed upright. Thus by overfilling the device, some of the anatomic shape of the device—in particular, the contour of the upper pole—is lost, and the variably overfilled implant actually can develop a mild bulge in the upper pole. Therefore, paradoxically, many surgeons have noted that these devices, rather than affording control of the upper pole of the breast, actually resulted in distortion of the upper pole. To some extent this observation was responsible for many surgeons remaining skeptical about the anatomic concept until the introduction of cohesive gel allowed the anatomically shaped shell to be used more effectively.

Problematic upper pole control with anatomically shaped saline implants was more common with full height devices. Shorter height implants were less prone to upper pole distortion simply from a mechanical perspective, since there was less implant to potentially overfill the upper pole of the breast, and many surgeons were able to use these devices to good effect. No matter what the potential disadvantages may be, anatomically shaped saline implants played an important role in the development of the shaped implant concept. During the early 1990s, when there was a moratorium on the use of silicone gel implants imposed by the FDA in the United States, the saline implant was all that was available, and it was this experience that guided the subsequent development of the current generation of anatomically shaped cohesive gel implants.

Implant Selection

The goal in choosing a specific implant for a particular patient is to select a device that will optimally complement the patient's existing anatomy to create the most aesthetic result possible. To a certain extent, this goal can be influenced by the desires of the patient regarding breast size and shape. To this end, a series of measurements can be made preoperatively that directly guide implant selection.

Preoperative Measurements to Guide Implant Selection

Clavicle-to-Nipple Distance

The clavicle-to-nipple measurement provides a gauge to assess the degree of breast ptosis. Although many other variables can influence this measurement, distances of more than 19 to 20 cm indicate a low-riding nipple, and the surgeon may consider a combination mastopexy and augmentation. Perhaps more useful is the observation that this distance can potentially be different from side to side. Such asymmetry can either result from an asymmetrical shoulder cant or clavicle position or from a true asymmetry in nipple position. It is important to point out such asymmetries to the patient ahead of time so she knows that these differences may well still be present after the augmentation, or together with the surgeon she can consider procedures designed to correct the asymmetry.

Sternal Notch-to-Nipple Distance

The distance from the sternal notch to the nipple, measured on both sides, is a truer indicator of nipple-areola complex asymmetry, since the variables of shoulder cant and clavicle position are removed.

Intermammary Distance

The intermammary distance is determined by gently translocating the breasts together medially in an attempt to reproduce the contour that will be created by an implant. With this maneuver, some women will develop cleavage to the point where the breasts actually touch. Others will maintain a variable distance between the breasts. This assumes that the pocket dissection will not extend past the internal mammary perforators and onto the thin presternal skin. It is important to discuss this aspect of the breast augmentation result with the patient, because many women will assume that their breasts will touch in the midline after the procedure. If the preoperative anatomy will not allow this, it must be pointed out ahead of time to avoid any patient misconception.

Areolar Diameter

The horizontal width and height of the areola without tension is noted and used as a guide to predict how big the areola could potentially become after an implant is placed. If the size of the areola becomes excessive postoperatively, the quality of the final result can be compromised. In these situations, the potential need for an areolar reducing procedure can be discussed as part of the overall operative plan.

Inframammary Fold-to-Nipple Distance Without Stretch

The distance from the inframammary fold to the nipple serves as an indicator of the amount of skin available to stretch over the implant. When this distance is short (less than 5 cm), it is best to consider using a moderate (low) profile implant that will not require a great deal of skin to wrap around the inferior pole of the device. When this distance is excessive (more than 8 cm), a high profile implant to fill out the redundant skin envelope with or without a mastopexy should be considered. For distances between 5 and 8 cm, a moderate plus (medium) profile implant will usually suffice.

Inframammary Fold-to-Nipple Distance With Maximal Stretch

To assess the elasticity of the lower pole skin envelope, the distance from the inframammary fold to the nipple is measure with the tissue under maximum stretch. As with the static inframammary fold-to-nipple measurement, this information can affect the choice of implant projection. When the lower pole skin stretches only 2 cm or less, there is tight skin envelope and a lower profile implant may be the best choice. When the skin stretches 3 cm or more, a higher profile device will more effectively fill out the lower pole of the breast.

Breast Base Diameter

The base diameter of the chosen implant must fit comfortably within the confines of the patient's preexisting soft tissue framework. A linear caliper is used to estimate the width of the breast that will result after the breast has been augmented. This measurement extends from the medial border of the breast, just lateral to the location of the internal mammary perforators, over to the proposed new lateral border of the breast. This measurement is termed X.

Medial Breast Pinch Thickness

With a pair of skin fold thickness calipers, the horizontal skin fold thickness of the medial breast is measured by pinching the skin together with the forefinger and thumb of the left hand so that a horizontal skin fold is created. By dividing this measurement in half, the thickness of the medial soft tissue layer that covers the medial aspect of the implant can be determined. This measurement is termed Y.

Lateral Breast Pinch Thickness

A similar measurement is made laterally to determine the lateral soft tissue thickness. This measurement is termed Z.

Breast Implant Calculation

The base diameter of the implant that will optimally fit the patient can be selected by subtracting the medial and lateral soft tissue thickness from the proposed breast base diameter, or

$$X - (Y + Z)$$

This measurement simply represents the average base diameter that will comfortably fit within the measured soft tissue framework. It is possible to underselect this measurement by up to 1 cm to meet the needs of a patient who wants only a modest increase in breast size. However, underselecting a base diameter by more than 1 cm risks creating a contour deformity from incomplete filling of the soft tissue envelope of the breast. Conversely, it is also possible to overselect this measurement by up to 2 cm, depending on the patient's wishes. In this circumstance, the position of the inframammary fold will also likely have to be adjusted lower to accommodate the increased dimensions of the device. In other words, there is a certain tolerance to the measurement of the breast base diameter, and this dimension can be manipulated to a certain extent to satisfy a specific goal.

Upper Pole Pinch Thickness

The soft tissue thickness of the upper pole of the breast can be assessed by pinching the skin fold at the level at which the upper border of the implant will be located. If the soft tissue cover measures 2 cm or more (or a 4 cm doubled over skin fold mea-

surement), the subglandular plane can be used for implant placement without risk that the superior implant border will be visible. A measurement of less than 2 cm may result in a visible implant shadow along the upper-inner quadrant of the breast if the subglandular plane is used. Of course, other factors, such as implant shape, volume, fill, and soft tissue elasticity can also have an impact.

Patient Desires

One of the most important elements of the preoperative evaluation process is to assess very clearly what the patient wishes to achieve as far as the size and shape of her breasts postoperatively. In the past, discussions based on cup size using the A, B, C, D, DD sizing system have proved incomplete at best and inaccurate at worst. A better way of communicating this would be based on the patient's preexisting anatomic limitations and how those limitations can affect the final result. To this end, I have found the following classification system to be very useful for ensuring that the result the patient and I have in mind is as similar as possible:

Type 1: A small breast implant is used if the patient does not want the size of her breast to be noticeably increased. Such patients are often simply seeking a modest filling out of an underfilled and ptotic postpregnancy skin envelope. A larger implant could easily be used, but the patient does not want that degree of breast enlargement.

Type 2: The patient's overriding concern is for the breasts to be as large as possible, but not to the point at which the shape begins to appear unnatural. In particular, the slope of the upper pole of the breast must be straight, with no telltale bulging to suggest that an implant has been placed.

Type 3: A larger implant is used to create an overly full upper pole and complete filling of the skin envelope. When the patient wears a bathing suit or a low-cut dress, it may be clear to the casual observer that the results appear augmented.

Type 4: The largest implant that can be inserted under the available soft tissue framework is used, with no regard for the unnatural shape of the breast that results.

Discussing this with the patient and attempting to understand what type of result she desires can provide useful insight into the type of implant that can provide the optimal result. This can minimize the reoperation rate for size change after initial breast augmentation and increase patient satisfaction.

The evaluation parameters described in this section form the basis for the BodyLogic implant selection system. The data sheets, required calipers, and implant selection guides are commercially available from Mentor.

Indications

Round

Round implants continue to play a dominant role in breast augmentation, and for good reason—an excellent result can be achieved in the vast majority of patients with round gel or saline implants. Using the measurement parameters described earlier, an appropriate round implant can be chosen to meet the needs of each patient by matching the base diameter, volume, and projection in the best way possible to create the desired result. Certain features concerning round implants bear emphasis, however. When saline implants are used, the volume in the device must be at or even slightly beyond the stated fill volume to prevent wrinkling in the implant shell. Thus these devices tend to create a more rounded contour in the upper pole, and, when this is taken to the extreme, can noticeably distort the breast. Conversely, round gel implants are always variably underfilled and will fold and wrinkle once placed in the pocket. The folds and wrinkles that form tend to be softer, with edges that are less sharp than those that form with saline devices; therefore the wrinkles are better tolerated. These devices also have a softer feel to them. Because of this ability to fold and conform to the overlying soft tissue framework, round gel implants offer a very versatile option for breast augmentation; a full, natural shape is developed with less chance for upper pole contour deformity.

Whether saline or gel, round devices continue to play an important role in the breast augmentation practices of surgeons around the world.

Anatomically Shaped

It would not be an oversimplification to state that every breast augmentation patient is a candidate for the use of an anatomically shaped cohesive gel breast implant. The concept is that powerful, and the results can be that outstanding. The ability to directly control the contour of the breast by using the implant to create the desired shape offers the surgeon control over the operation. With that as the basic premise, one must then step back and evaluate the other variables and balance the potential complications against the results obtained with round implants, sincere there are several potential drawbacks associated with the use of cohesive anatomically shaped gel implants.

Drawbacks to the Use of Anatomically Shaped Cohesive Gel Implants

ROTATION It is self-evident that an anatomically shaped implant must remain in the proper orientation to produce the desired shape. If the implant rotates, control over the shape of the breast is lost, and the breast becomes distorted.

STIFFNESS Although the cohesive gel supports the implant shell and helps create the device's shape, these implants have a stiffer feel than the more traditional round gel implants. Some patients may find this firmer feel objectionable.

COMPLEXITY The implant selection process and the operative technique are more involved with anatomic devices than with round implants; therefore greater emphasis must be placed on accurate measurement of the patient and on more exacting surgical technique. In short, there is less tolerance for inaccuracy when using shaped devices.

COST Anatomically shaped cohesive gel implants are more expensive than comparable round devices.

These variables, in particular the possibility of implant malposition with rotation, must be weighed against the advantages of the shaped design. In general terms, if the results obtained using a round device on one side and a cohesive shaped device on the other were to be indistinguishable, it is a better option to use the round device to avoid these potential complications. With that in mind, however, there are several subsets of patients who are particularly good candidates for anatomically shaped cohesive gel implants.

Suitable Candidates for Anatomically Shaped Cohesive Gel Implants

PATIENTS WITH HYPOMASTIA In patients with small breasts in whom the implant would provide 75% or more of the overall final breast volume, an anatomically shaped device will provide better control over breast shape than a round device would. In such patients, the ability to control the upper pole and maximize lower pole projection allows the surgeon to create very aesthetic results, particularly when used in the subpectoral position, where the muscle can be used to soften the pe-

ripheral upper pole contours. In these patients, using a cohesive gel anatomically shaped device can create a more natural result for a given volume than a round implant can. Reconstructive patients who have relatively thin mastectomy flaps and revisionary patients who have undergone multiple procedures with thinning of the soft tissue framework of the breast can benefit from selection of a cohesive gel shaped implant. As with primary hypomastia, the ability to directly shape the breast allows the surgeon to more definitively control the quality of the aesthetic result.

This 32-year-old woman requested breast augmentation. Because of her significant hypomastia, a textured anatomically shaped cohesive silicone gel implant was selected to fill out the breast-skin envelope. She is shown 2 years after placement of 355 cc (321 CPG) mid height low profile textured cohesive anatomic silicone gel implants in the subglandular plane. An overall aesthetic augmentation of the breast has been achieved.

PATIENTS WITH PSEUDOPTOSIS Patients who present with a properly positioned nipple-areola complex but have ptosis of the lower pole with an excess of skin and parenchyma in the lower pole are particularly good candidates for breast augmentation using anatomically shaped cohesive gel implants. Because more of the gel is located in the lower pole of the anatomic implant, a more proportional filling of the lower pole of the breast results from its use and this can provide results superior those obtained with round devices.

This 44-year-old woman requested breast augmentation to correct her pseudoptosis. Textured anatomically shaped cohesive gel implants were chosen to fill out the lower poles of her breasts. She is shown 2 years after placement of 321 CPG mid height low profile textured cohesive anatomic silicone gel implants in the subglandular plane. Aesthetic augmentation of the lower poles of the breast has been achieved without creating any distortion or excessive fullness in the upper poles of the breasts.

Patient Request

The safety profile associated with anatomically shaped cohesive gel breast implants is impressive. Perhaps no other implant has provided such outstanding aesthetic results with fewer complications. For this reason, many patients who are knowledgeable about implant selection often request information about these devices. At this writing, these implants are still available only as part of an FDA-sponsored study. Once they do become available for general use, the popularity of these devices is likely to increase significantly.

Concluding Thoughts

The overriding goal in choosing an implant for use in aesthetic and reconstructive breast surgery is to pick a device that will complement the patient's existing anatomy and provide the best aesthetic result possible. By thoughtfully combining the various choices in shape, fill, and texture, implants appropriate for each patient can be selected that will maximize the quality of the aesthetic result and minimize complications.

Clinical Caveats

The patient's desires should be assessed and discussed preoperatively regarding size to avoid patient dissatisfaction.

A selection system based on the patient's anatomy rather than on cup size is preferable.

A repeatable measuring technique must be developed to enhance consistency.

Base diameter, volume, and projection are combined to optimize implant selection.

When possible, the bigger of two implants should be chosen when both will fit the soft tissue framework.

CHAPTER 62

Breast Augmentation

GLYN JONES

Breast augmentation is one of the most popular aesthetic surgery procedures performed in the United States today. Each year more than 250,000 women elect to have their breasts enlarged, despite unresolved questions about implants and long-term problems such as capsular contracture. Typically performed to enhance the size of normal but small to moderate-sized breasts, this operation can also help to restore balance to asymmetrically sized breasts. Although breast augmentation is a procedure with a high level of patient satisfaction, it is less routine than its description would suggest. Critical decisions concerning the choice of implant, surgical approach, and implant placement are essential to ensuring a satisfactory result. Even with meticulous surgical technique, the operation is dependent on the design and efficacy of the implantable device and the body's reaction to this foreign material. Capsular contracture remains the most persistent and troubling of potential complications associated with these devices. As a result, creating a long-lasting, soft, and natural-appearing augmented breast continues to challenge the surgeon's skill and ingenuity.

Evolution of Technique

The introduction of the silicone breast implant in 1963 marked the beginning of breast augmentation as we know it today. Since its inception, this operation has evolved with the development of new implantable devices with improved shell and filler technology to enhance patient outcomes and to provide surgeons with a range of treatment options. The popularity of this operation declined with the breast implant controversy of the early 1990s, when the FDA restricted access to breast implants filled with silicone gel because of fears about complications and possible links to disease. These fears have largely waned over time as new scientific studies and clinical trials have provided considerable information about the safety and efficacy of these devices. Demand for breast augmentation today is even stronger than it was before the controversy arose. However, restrictions placed on silicone gel implants by the FDA have served to substantially limit implant availability in the United States.

The search for the ideal implantable device has long shaped the evolution of this operation. The quest is for a device that is soft, natural, long-lasting, containing a biodegradable filler, and radiolucent. The filling used is an important factor in obtaining this ideal. Early breast implants were filled with silicone gel. Experience with these implants revealed that capsular contracture was a possible complication, which led surgeons to develop saline-filled implants as a possible alternative. Although saline-filled devices reduced capsular contracture to some extent, the incidence of contracture remained frustratingly high. The quest for alternative fillers continues to

this day. Implants with lipid fillers have been tried but abandoned. Although they were radiolucent and allowed improved visualization during mammography, they were not biodegradable. Furthermore, reports of granulomas and a percutaneous rancid odor made them unacceptable. While surgeons in the United States were dealing with FDA restrictions on implant usage, the search for alternative fillers was ongoing outside the United States. Several companies developed cohesive silicone gel implants for use elsewhere in the world. The first generation of these cohesive gel devices was very stiff; however, newer cohesive gel fillers have a softer, more natural feel and are now the primary implant choice of surgeons in most countries outside the United States. The FDA has lifted its ban on silicone gel-filled implants for cosmetic breast augmentation in the United States; these devices are now widely used in this country and account for a substantial percentage of the devices inserted for breast augmentation. Cohesive form-stable gel devices have not been approved by the FDA for general usage, but it is hoped that they soon will be.

The shape and texture of implant surfaces have also evolved over time. Early implants were round and smooth. Over time, to reduce the incidence of capsular contracture, different surface coatings and textures were developed. Polyurethane-coated implants produced a dramatic drop in the rates of early capsular contracture. Contractures were reduced by the inflammatory response that was induced when polyurethane foam came into contact with tissue, as well as by the large surface area of the resulting capsule over the convoluted surface of a foam shell. Unfortunately, as the polyurethane foam degraded, it exposed the underlying smooth gel implant core, leading to a slow rise in capsular contracture formation beyond 10 years after insertion. Favorable reports on the softness and performance of polyurethane-covered implants, which are no longer available in the United States, combined with studies of the relationship of physical surface properties to biological reactivity of the implants, led to the development of the textured-surface breast implant in 1987, which mimicked the foam surface of polyurethane. This stippled texturing had some limited benefit, although it was never as effective as polyurethane. It was also noted that the density of the surface texturing affected its ability to adhere to the tissues; the denser or deeper the texturing, the greater the adhesion. Some surgeons believe this texturing has been beneficial in reducing capsular contracture; however, the addition of texturing has also resulted in thickening of the implant wall, with increased palpability and visible rippling. Although these features have detracted from the advantages of texturing, the new surfaces have also facilitated the development of realistically shaped implants, which have become popular in recent years. These anatomically shaped devices provide greater flexibility in breast shaping, but rotation of the devices may cause unsightly deformation if the pocket is too large; more aggressive texturing may limit the problem of implant rotation.

Surgical approaches and planes for breast augmentation have also evolved over time. Initially, breast augmentation operations were performed through an inframammary incision accessing the subglandular plane for gel implant insertion. The inframammary subglandular approach gave way to total submuscular placement to reduce capsular contracture and implant visibility. Total submuscular coverage has in turn yielded to a trend toward biplanar placement in which the implant is partially submuscular and partially subglandular in its lower pole. Although both of these goals were achieved to some extent, there has been an interesting swing back toward subglandular placement to achieve better breast shape.

The inframammary approach remains the most common augmentation approach used worldwide, followed by the periareolar approach. Transaxillary augmentation was popularized in 1973, but many surgeons abandoned the technique when problems arose related to implant malposition, asymmetry of the inframammary creases, and control of hemostasis from a remote-access site. The technique was resurrected at Emory University in 1993 when endoscopic approaches made more precise dissection and implant placement possible. Endoscopy also paved the way for the development of the transumbilical approach to breast augmentation (the TUBA procedure). Although this technique is not popular, some surgeons have achieved pleasing results with it. Initial problems with the use of the implant as a pocket expander that resulted in voiding of the implant warranty led the pioneers of this technique to advocate the use of a balloon expander or temporary sizer to create the pocket, with subsequent permanent implant insertion at the end of the dissection. This has led to wider acceptance of the technique.

Advantages and Disadvantages

Breast augmentation is an operation that has a high degree of patient acceptance. It offers definite advantages for patients who seek larger breasts or correction of breast asymmetries. It can produce enhanced breast shape, increased cleavage, some breast lift in individuals with early ptosis, and balance for patients with constricted or tubular breasts. It can also improve a patient's body image and even make her clothes fit better. Breast augmentation has no negative impact on breast-feeding ability, no proven causal relationship with systemic illness, and no link to cancer. In fact, studies have found that breast augmentation may contribute to earlier cancer detection in augmented patients when compared with the unaugmented population.

The major disadvantage of breast augmentation is the significant risk for the development of capsular contracture as well as the possibility that some revision surgery will be required in the future to replace the implants, because implants are not life-

time devices. Reoperation may also be required to address breast distortion and asymmetry that may occur as capsular contracture develops.

Other implant-related problems that may develop include implant rupture, with deflation, leakage, wrinkling, and possible palpability of the implants. The fact that breast implants feel cooler than natural breast tissue, especially in thin, small-breasted women, is also a negative for some patients. Finally, implants may obscure breast tissue, making it more difficult to identify breast problems on mammograms and requiring special views to more effectively image a woman's breast tissue.

Indications and Contraindications

Breast augmentation is indicated under the following circumstances:

- To augment the breasts in women with hypomastia
- To provide a mastopexy effect in women with mild to moderate ptosis
- To provide symmetry in women with developmental anomalies of the breast (for example, Poland's syndrome and constricted breast deformity)
- To provide symmetry in women undergoing breast reconstruction
- To provide upper pole fullness in women with volume loss after pregnancy or massive weight loss, who require both mastopexy and augmentation

The following are contraindications for breast augmentation:

- Women with body dysmorphic disorder and other psychiatrically unstable patients
- Women hoping to salvage a marriage or relationship or to find a husband by having bigger breasts
- Women with collagen vascular disease (these individuals should be advised against breast augmentation in the current legal climate, even though there is no proven cause-and-effect relationship between collagen vascular disease and breast implants)
- Women with severe fibrocystic changes, ductal hyperplasia, and/or atypia whose breasts are difficult to image well or in whom there is a high risk of breast cancer (implants in these women make mammographic screening even more unreliable and may be relatively contraindicated)
- Women under 18 years of age should be discouraged from having augmentation, because they may not appreciate the long-term implications of implantation of a foreign device
- Women who want the procedure in response to spousal, parental, or peer pressure to have the procedure

Pertinent Anatomy

The female breast sits on the pectoralis major muscle overlying the second through the seventh ribs. The nipple is situated at the midclavicular line over the fourth rib in a youthful, nonptotic breast. The tail of Spence extends up toward the axilla over the inferolateral border of the pectoralis major muscle and merges with axillary floor fat. The intercostobrachial nerve crosses the axillary floor in its course to the medial arm and may be at risk during transaxillary dissection.

The breast parenchyma is divided into lobules like the segments of an orange, each segment having its own set of draining ducts that terminate in the nipple. This separation is only apparent on ductography.

The blood supply to the breast consists of a complex interlacing system of vessels arising from the internal mammary perforators, the cutaneous branches of the intercostal vessels, the thoracoacromial vessels, and the lateral thoracic vessels, together with a small contribution from the crossing branch to the serratus anterior from the thoracodorsal system.

The nerve supply is from the intercostal nerves (second to seventh); the primary supply to the nipple is derived from the fourth intercostal nerve.

The breast is suspended from the pectoralis major muscle fascia and to some extent by the suspensory ligaments of Cooper. These have to be divided during subglandular augmentation. The inframammary crease is a discrete anatomic structure that may be very tightly developed in some women with hypomastia, particularly those with constricted breasts. Releasing or lowering this anatomic landmark may require radial scoring of the parenchyma up to the dermis in selected cases. Thin patients

with widely separated breasts often have a significant expanse of poorly padded skin overlying the intermammary area and sternum; this may provide inadequate coverage for an implant and result in significant visibility of the implant.

Preoperative Assessment

Physical Examination

A thorough medical history should be taken, including direct questions about any family history of breast or ovarian cancer. I have seen several patients with a history of these cancers who subsequently tested positive for the breast oncogenes when screened. A thorough physical examination should be performed, paying particular attention to evaluation of the skin, nails, and joints for signs of collagen vascular disease and compressive neuropathies.

The surgeon should assess height and weight relationships, particularly the length and width of the chest and trunk. Skin quality and the thickness of subcutaneous fat have a significant impact on the choice of implant location—the thinner the patient, the more likely she is to benefit from submuscular coverage of the implant to mask rippling.

Breast symmetry should be carefully evaluated, and any preoperative differences should be documented photographically and pointed out to the patient. Nipple levels should be measured and differences noted. Nipple size and sensation should also be assessed. The level and tightness of the inframammary fold should be evaluated, and any plan to drop this fold should be discussed with the patient, because this may affect the fit of a bra. The size and thickness of the pectoralis major muscles should be evaluated, because very active, muscular patients often do better with subglandular augmentation than submuscular placement, since the latter may result in rhythmic displacement of the implant during heavy upper body exercise. Finally, and most important, the breast should be examined for masses. The role of preoperative mammography remains a vexing question. I prefer to have mammograms taken of any woman over the age of 35 who is contemplating aesthetic breast surgery.

Patient Education

Patient education is vital during consultations, because breast augmentation has one of the highest incidences of short-term and long-term complications of virtually any cosmetic operation performed today. All complications should be listed and discussed individually with the patient, particularly capsular contracture, rippling, deflation, impact on mammography, and nipple sensation. The potential link with autoimmune disease should be discussed and placed in proper perspective, and patients should

also be reassured that breast-feeding will be unaffected by this procedure. Informative literature should be made available as a routine part of any consultation, and high-quality photographic documentation is essential. If patients are part of a gel implant study, all pertinent documentation should be completed meticulously to satisfy study guidelines. Although breast augmentation often requires subsequent revision surgery and patients need to be informed of that possibility, most patients remain extremely satisfied with this procedure and believe they understand its complications and that its benefits far outweigh the risks.

Preoperative Planning

Determining Breast Volume

The patient's concept of her ideal breast size strongly influences the ultimate decision about breast volume. I always inquire what the patient thinks of her present breast size and ask her to bring in a padded bra or a picture that provides a better indication of a breast volume that is more to her liking. Photographs that illustrate women whose breast size approximates the size that she desires can provide a good indication of the degree of enhancement that the patient is looking for. Digital imaging can also facilitate communication when trying to determine the appropriate breast size. By using an imaging system, the surgeon can demonstrate the various size increases and the resulting impact these will have on body proportions. When using such an imaging system, it is important to emphasize to the patient that no guarantees are implied by the morphed images. This imaging is intended only to give the patient an idea of possible changes and how they would look, and to help her to understand the various treatment approaches from which she can choose.

Implant Selection

Implant Fill

Implant selection is influenced in part by the availability of devices. Outside the United States, cohesive gel-filled form stable implants have become the benchmark for breast augmentation as well as implant-based reconstruction. Cohesive gel implants have been used in Europe since 1995 and have been available in Canada since 2000 through special approval by Health Canada. One of the advantages of the newer generation cohesive gel-filled implants is that they feel more natural. Compared with saline-filled breast implants or even conventional gel filled devices, rippling is less common because they are semisolid. Deflation is also not a problem with

cohesive gel implants, and if a cohesive gel implant ruptures, it still maintains its shape and integrity. There are also a number of implant models with varying projection, height, and width, so there is some flexibility in selecting the best implant size to balance body proportions and breast aesthetics. A disadvantage of cohesive gel-filled implants is that they require a slightly larger incision for insertion because they are semisolid; they are also more expensive. These implants are usually placed through an inframammary incision.

Surface Texture and Shape

The surgeon must also choose between textured or smooth and round or shaped implants, with low, medium, or high profiles. Textured devices have a somewhat lower capsular contracture rate than smooth implants, but they have thicker walls and greater palpability. Texturing may also cause higher rupture rates, but these data are not conclusive. In general, smooth-walled implants are preferable for use in very thin-skinned patients to diminish implant palpability. Textured devices are better tolerated in thicker-skinned women or those with modest amounts of breast tissue.

Round implants work very well in most women, but some surgeons prefer the appearance of anatomically shaped implants. When the upper pole of the breast is deficient, anatomic implants may be particularly helpful, because they can create the impression of a gentler taper onto the chest wall than a round implant might achieve.

A high profile implant has greater anterior projection with a smaller base diameter than an equivalent moderate profile implant. High profile implants are best used in women who want significant anterior projection, as well as in narrow-chested women in whom the use of a larger-diameter device may cause unsightly underarm bulging.

Note the difference in projection between high profile (*left*) and moderate profile (*right*) implants.

Size

In general, it is wise to use implants with volumes of less than 400 cc for breast augmentation; larger volumes tend to be associated with higher complication rates, including complications such as gravitational ptosis.

This 32-year-old woman was referred to me for a second opinion after she had had 450 cc saline-filled implants inserted through an inframammary approach. Overdissection inferiorly and medially, combined with the use of large implants in an effort to produce cleavage, produced a catastrophic result, with imminent erosion inferomedially, derotation of the nipples, and incipient synmastia. The ultimate clinical outcome of this case is unknown.

In recent years there has been a trend toward evaluating implant size based on implant and breast diameter rather than total reliance on implant volume. Although it is true that implant projection increases with volume, it is also notable that implant base diameter increases with volume. Added to this is the fact that a moderate profile implant has a much broader base diameter than an equivalent-volume high profile implant. A narrow-chested woman may benefit more from a high profile implant with a narrower base diameter so as to minimize the risk of the implant bulging into the axilla than she would if a broad-based moderate profile implant were inserted.

Volume requirements are also influenced by the patient's weight: volume requirements become more extreme and the results less satisfying for overweight patients. Although a 220 cc implant will provide good contour improvement for a thin patient, this same implant will not provide adequate contour enhancement for an obese patient.

Measurement of the breast dimensions with calipers provides a reasonable estimate of the implant base diameter required to achieve an appropriate augmentation and can serve as a guide as to whether a patient would be a good candidate for a moderate or high profile implant. Breast diameter as well as medial and lateral breast tissue pinch thickness can be used to determine implant volume.

If the base breast diameter in centimeters is X , the medial pinch thickness is Y , and the lateral pinch thickness is Z , then $X - (Y + Z) =$ the base diameter of the average-sized implant that will fit comfortably beneath the skin envelope. Part of this decision-making process depends on the patient's preference about perceived projection of the final breast shape. Implant companies provide surgeons with detailed tables of implant dimensions including the length, width, and height of any given implant volume; moderate and high profile dimensions and anatomic shape also factor into these tables. (See the Appendix on pp. 2271 through 2277.)

Adjustable Implants and Temporary Sizers

Adjustable implants first appeared on the market in the form of the Becker expander-implant, a double-lumen, gel-saline expander with a pull-out fill tube mechanism. The device is used for breast reconstruction and is designed for permanent placement once expansion to the required volume has been achieved.

The Siltex Spectrum implant is an extension of this principle as applied to breast augmentation. It is a textured saline-filled implant with a pull-out filler mechanism that allows for postoperative volume adjustment once implanted. The device is useful in patients who have breast asymmetry or those who are unclear about what size they would like to achieve. The devices have a leeway of only about 50 to 60 cc once filled, so major changes in volume are not possible.

Adjustable implants carry the risk of deflating when the fill tube is removed, because the valve seal can fail, either early or late. Also, valve removal mandates a second minor procedure in the office, and additional scarring may develop at the site of removal.

Temporary intraoperative saline sizers provide an alternative to adjustable implants. Sizers allow a high degree of intraoperative accuracy in volume assessment, particularly in patients with asymmetrically sized breasts. (See the Appendix on pp. 2271 through 2277.)

Incision Placement

Incision placement is largely dependent on surgeon and patient preferences. There are three basic choices: inframammary, axillary, and periareolar. The transumbilical approach is also used but is less popular than the others. If a patient has a well-defined inframammary crease with mild ptosis, an inframammary incision is easily camouflaged postoperatively. However, if the crease is almost nonexistent, as is the case for patients with severe hypomastia, an axillary placement is preferable. Periareolar incisions are useful in patients with normal to large areolae, but many patients with marked hypomastia have small areolar diameters that do not lend themselves readily to this approach. If a woman has major concerns about nipple sensitivity, it is probably unwise to employ a periareolar approach.

When using the inframammary approach, I prefer to place the incision approximately 1 to 1.5 cm below the existing crease; this allows the scar to glide up into the new breast crease, since the augmentation recruits inframammary skin up onto the breast mound. Failure to perform this simple maneuver results in the scar's creeping up onto the lower breast mound and becoming more visible. Incision lengths should be kept to a minimum, preferably less than 5 cm.

Implant Position

The optimal implant position must also be determined. There are three options: subglandular placement, submuscular placement, or biplanar placement, which is partially submuscular and partially subglandular in its lower pole. Advocates of the subglandular approach believe that it produces a better breast shape. Those who prefer the submuscular approach believe that the layer of muscle over the implant has a cushioning effect, thereby promoting a softer breast with less potential for capsular contracture. The biplanar approach combines the benefits of both approaches.

This 28-year-old woman was referred to me for correction of high-riding implants caused by incomplete inferior dissection, as discussed earlier. A transaxillary endoscopic inferior capsulotomy was done, with her implants left in situ during the procedure. Note the lowering of the inframammary crease bilaterally.

Patient Position

The patient is placed supine on the operating table with her arms stretched out. The arms should be well padded and wrapped onto the arm supports with wool padding to allow the patient to be flexed to an angle of 80 to 90 degrees with safety. This allows accurate intraoperative assessment of implant position in the erect posture; however, it does place the pectoral muscles under tension. The table should be able to break at the waist and flex to an angle of 90 degrees. If a transaxillary endoscopic augmentation is planned, draping should allow access for the surgeon above the arms during the endoscopic portion of the procedure.

Markings

Incorrect scar placement
in relation to inframammary fold

Correct scar placement
1 cm below inframammary fold

The inframammary crease is marked, as is the upper pole of the breast. The midline is marked at the intermammary space. If the inframammary fold is to be adjusted inferiorly, the degree of lowering should be clearly marked and the patient made aware of the new location. The location of the incision and its length are then marked. If an inframammary approach is planned, the incision should be placed 1 cm below the natural crease because recruitment of abdominal skin up onto the new breast mound will inevitably pull the scar into the new crease. Failure to carry out this maneuver results in scar migration into a visible position on the breast mound.

Periareolar incisions should be placed at the juncture of the areola and breast skin, not within the areola itself; any tendency to whitening of the scars will make a scar within the areola very visible.

Transaxillary markings should be placed high within the axillary floor; the surgeon should be careful to keep the anteriormost limit of the scar away from the anterior axillary fold, where it may be visible in sleeveless clothing. In patients with breast asymmetry, the incisions are placed to reflect the final breast shape and position of the

inframammary fold. If a patient has a higher crease on one side than the other, the higher crease should be lowered to match the normal opposite crease, and the scar placement should be positioned lower to reflect the new crease position.

Treatment Algorithms: Choosing the Best Augmentation Approach

At present, I perform the bulk of breast augmentation procedures through an inframammary incision into the biplanar subpectoral plane in an effort to reduce capsular contracture. This comes at the expense of less projection per cubic centimeter of implant volume and a slightly less pleasing shape. There is no doubt that subglandular augmentation provides better shape and projection overall. Subglandular augmentation is best performed in active or muscular individuals with reasonable subcutaneous padding and a moderate-sized breast to start with. This provides the best implant camouflage and reduces the incidence of visible implant ripples and wrinkles. Very small-breasted women with little or no fold definition are well suited to transaxillary augmentation, as are patients with a propensity for keloid formation, such as women of Asian or African heritage.

Options for Patients With Asymmetrical Breasts

Patients with asymmetrical breasts present unique challenges because of the potential for residual postoperative asymmetry. Breast shape may be complicated by associated ptosis as well as constricted breast deformity. Selection of asymmetrical implant sizes will correct the problem, and the use of saline-filled implants can be really helpful, because they allow some degree of intraoperative adjustment to correct subtle residual differences in breast size. In more complex or severe cases, mastopexy may be necessary, at least on the more ptotic side, a problem that requires patient

acceptance of more extensive, asymmetrical scar placement. In patients with constricted or tubular breast deformity, extensive release of the lower pole of the affected breast may be necessary, and in more severe cases, initial tissue expansion may be the only recourse available to the surgeon. The surgery of constricted or tubular breasts is not the topic of this chapter, but a basic algorithm for the patient with asymmetrical breasts is useful.

Operative Technique

Inframammary Approach

With the patient in the supine position, an inframammary incision is made through skin and subcutaneous fat. Dissection is carried down to the pectoral fascia, retracting the breast in a cephalad direction. The lateral border of the pectoralis major muscle is grasped with an Allis clamp and after the muscle edge is elevated, the subpectoral plane is entered with blunt scissors dissection.

Once entered, the subpectoral plane can be bluntly dissected with either gentle finger dissection or a metal sound or breast dissector. At this point dissection is entirely blunt, with no attempt at muscle avulsion. The cavity thus created is now visualized by inserting a fiberoptic illuminated retractor with suction incorporated.

Under direct vision, the medial pectoralis major fibers are divided with cautery from the 3 to 6 o'clock position on the right and the 6 to 9 o'clock position on the left. Muscle division may be carried through the muscle belly until the grayish-white color of the prepectoral fascia is visualized or until fat is just visible. Some authors recommend leaving the muscle intact to prevent visible implant ripples and wrinkles in the cleavage area. Overdissection medially may result in synmastia with time, a problem that is extremely difficult to correct.

Overdissection in an inferomedial direction may result in an unattractive, boxy appearance to the medial breast, as seen in this woman, who required correction by open capsulorrhaphy, with nonabsorbable sutures tacking the dermis to the underlying rib periosteum. The pocket size and location should be created to place the implant exactly where it is wanted.

Care should be taken when releasing the inframammary crease to prevent abnormally low implant descent with pseudoptosis and derotation of the nipple areola complex.

Laterally the implant pocket is opened with blunt finger or breast dissector stripping. The loose areolar tissue in this area offers little resistance, although occasionally muscle fibers from the lateral border of the pectoralis major may need division. Care should be taken to avoid overdissecting this area inferolaterally, because it can cause a lateral implant bulge that is extremely difficult to correct. Superior dissection should be kept to a minimum to limit the risk of development of excessive upper pole fullness. Once the pocket has been prepared, it is irrigated with either saline solution or an antibiotic solution containing gentamycin, bacitracin, and a cephalosporin. There is some evidence that this may reduce capsular contracture by limiting skin commensal bacterial contamination. Iodine-containing solutions such as Betadine should

not be used to wash the pocket, because they have been implicated in silicone implant wall compromise.

Symmetry of the dissected pockets is essential and should be carefully checked. With symmetrical pockets in place, temporary sizers may be used to evaluate the effect of different implant volumes on the final shape of the breast.

After further pocket irrigation, the definitive implants are selected and inserted. Before insertion, it is useful to apply an occlusive dressing such as Tegaderm or Ioban over the breast to prevent any contact of the implant with the skin. The surgeon's gloves should be changed at this juncture to further minimize implant contamination with bacteria. The use of a Keller funnel is another useful but currently expensive technique that can reduce bacterial contamination of the device during insertion. Implant position is carefully adjusted, particularly if textured surface devices are used.

Closure is performed in three layers with a running subcuticular suture, starting with a deep fat and fascial layer, followed by a subcutaneous layer. Steri-Strips and an adhesive transparent dressing such as Tegaderm or Op-Site are then applied, followed by a soft, supportive bra.

Results

This nulliparous 28-year-old woman requested breast augmentation and liposuction of her suprapubic area. She had small B cup breasts and well-formed inframammary folds, with modest suprapubic lipodystrophy. Inframammary subpectoral augmentation was performed with 275 cc smooth, round, saline-filled, high profile implants; liposuction was also done in the suprapubic area. She is shown 9 months postoperatively.

Inframammary augmentation was performed in this 27-year-old woman with a long, narrow chest and small B cup breasts. Her breasts were augmented with 325 cc smooth, round, saline-filled implants inserted in a subpectoral position. She is shown preoperatively and 12 months postoperatively.

Subglandular Approach

If a subglandular placement is planned, dissection is carried down to the pectoralis major fascia, and the breast gland is simply dissected off the muscle until an adequately sized pocket has been fashioned. Care should be taken medially, where internal mammary perforators may penetrate the breast from within the substance of the muscle; these should be meticulously cauterized. Care should also be exercised to not dissect too close to the skin to reduce the potential for visible wrinkling, palpability, and erosion. Implant placement, sizing, and closure remain the same as for partial subpectoral placement. Subglandular positioning will tend to provide more anterior projection of a given implant volume than would be the case with a partial subpectoral position.

Results

This 38-year-old woman with grade 2 ptosis requested a breast augmentation and lift without mastopexy scars; inframammary subglandular augmentation with 325 cc smooth, round, gel-filled implants was performed. She was willing to accept less-dramatic nipple elevation if she could avoid the scarring associated with a mastopexy. The lift produced by subglandular implant placement could not have been achieved with submuscular augmentation. Although this did not produce an ideal mastopexy effect, the patient was satisfied with the outcome, which achieved her goals.

This 32-year-old aerobics instructor specifically requested subglandular placement to minimize implant displacement during exercise. She is shown after inframammary subglandular augmentation with 300 cc smooth, round, saline-filled implants.

Periareolar Approach

The periareolar approach requires an adequate areolar diameter through which to operate. The incision should be made directly at the areola-cutaneous junction to best camouflage the scar. Attempts at placing the scar within the areola may result in the scar being visible if it turns white on maturation.

Periareolar access to the subpectoral plane through either subcutaneous or transglandular dissection

Dissection is begun subcutaneously over the breast and proceeds down to the inframammary fold. This is then lifted to expose the underlying pectoralis major muscle, which can then be elevated for a partial submuscular placement. Alternatively, a subglandular dissection is easily performed through this incision. Another technique used by some surgeons is to bisect the breast below the areola and approach the implant pocket directly through the substance of the breast. Either approach works satisfactorily, but patients should be warned of the potential for some sensory loss in the nipple-areola complex, usually temporary in nature.

Results

Periareolar subglandular augmentation with 325 cc smooth, round, saline-filled implants was performed in this 26-year-old woman with small C cup breasts. The patient had a pleasing result, with restoration of upper pole fill and enhanced cleavage.

Transaxillary Approach

The original transaxillary approach was an essentially blind operation that made medial visualization difficult for securing hemostasis or accurately dividing muscle fibers. The use of the endoscope has substantially improved the accuracy and predictability of this operation. Crease symmetry, muscle division, and implant positioning can be achieved with a greater degree of confidence and ease.

Equipment Required for Endoscopic Transaxillary Augmentation

- 10 mm 45-degree down-viewing breast endoscope
- Three-chip endoscopic camera with compatible O ring connector
- Emory breast retractor handle (right-angled handle) with incorporated suction port
- Fiberoptic cable with compatible connection to the endoscope
- Suction tubing
- Emory insulated cautery dissector and handle (right- and left-handed variants)
- Electrosurgical unit with appropriate connecting cable to the cautery dissector handle
- Blunt dissector (several designs available)
- Fog-reduction agent
- Long vertical container for warm saline solution to heat the endoscope lens for fog reduction
- Mobile wheeled endoscopic cart containing camera-video output and monitor with video recorder

The patient is placed supine on the operating table with adequate access above the arms for the operating surgeon.

Before surgery, if lowering of the crease is planned, the surgeon should mark the original inframammary crease as well as its new, lower location. The axillary incision is made in the midaxillary floor behind the anterior axillary fold to camouflage the scar adequately. The fat of the axillary floor is dissected with a blunt scissors-spreading action to prevent damage to the intercostobrachial nerve. The lateral pectoral fascia is opened by perforating it bluntly with closed scissors; with the use of a spreading action, the subpectoral plane is entered. This is facilitated by grasping the lateral pectoral muscle border between the thumb and index finger of the left hand while dissecting beneath it with scissors. Once the subpectoral plane has been breached, it can be bluntly opened up with an Emory dissector, Hegar dilator, or similar instrument. No attempt is made at this point to divide muscle fibers. The endoscope sheath is then inserted into the pocket while the endoscope itself is placed in warm saline solution or water to prevent lens fogging.

Transaxillary breast augmentation is illustrated, with endoscope insertion into the subpectoral plane. The planned muscle division is marked inferomedially. Once the retractor is in place, the warmed endoscope is inserted through the sheath. The orientation of the camera is carefully checked to ensure that the anatomy is correctly visualized. The toe of the retractor is pulled upward to expose the work face of the deep

surface of the pectoralis major muscle medially. Suction is connected, because smoke evacuation is vital to this part of the operation. Using a tested, insulated, spatula-tipped cautery, the medial muscle fibers are divided until the prepectoral fascia is seen; this marks the endpoint of dissection. The extent of muscle release is identical to that described for the inframammary approach. The pocket should be inspected carefully to ensure that division of the inferolateral muscle fibers is adequate.

The released pectoral muscle and pocket are bluntly dissected inferolaterally before the implant is inserted. Adequate inferior dissection is essential to correct implant position; failure to perform this maneuver may result in high-riding implants. The inferior dissection should match the external markings placed on the breast mound preoperatively if the surgeon plans to lower the breast crease. After the pocket is irrigated, the implants are inserted.

The implants are removed from their containers, fill tube valves are placed on the ends of the tubing, and a small volume of saline solution is instilled to remove any extra air. The deflated implant is then prepared for insertion by shaping it into a double row that is narrowed at the end for easier insertion.

The implant is inserted into the prepared submuscular pocket and inflated. Note its biplanar position.

The patient should be evaluated in the sitting position to establish conclusively that symmetry has been achieved and that the implants are not positioned too high. The axilla is closed in a two-layer fashion; no drains are placed. An transparent occlusive dressing is applied.

Results

This 26-year-old woman with very mild breast asymmetry requested breast augmentation with the least noticeable scar. Her right breast was slightly larger and more ptotic than the left. She had transaxillary augmentation with placement of 375 cc smooth, saline-filled implants inflated to 400 cc on the left and 375 cc on the right. She is shown 6 months after surgery; asymmetrical transaxillary augmentation improved her symmetry and achieved her goals of not having visible scars on the breast mound. A transaxillary scar is seen in the left axilla.

This young woman requested transaxillary augmentation. She is shown before and 1 year after augmentation with smooth, saline-filled moderate profile implants. The patient had an excellent cosmetic result with an enhanced, natural-appearing cleavage, fullness of the lower poles, and restoration of upper pole fullness.

Transumbilical Breast Augmentation

Transumbilical breast augmentation (the TUBA procedure) is performed through a superior periumbilical incision. Blunt dissection into the inferomedial aspect of the breast is performed, and a sigmoidoscope-like sheath is passed into the tunnel. A blunt dissector may be inserted into either the subglandular or subpectoral plane.

A balloon tissue expander is inserted and then inflated with saline solution to create the implant pocket. It is difficult to adjust the pocket with this procedure, and asymmetry or high-riding implants are potential complications. Once the pockets are dissected, the expanders are removed and the implants are inserted and inflated to volume before the fill tubes are removed.

Postoperative Care

Analgesia can be achieved with opiates, or the use of antiinflammatory agents such as nonsteroidal drugs and COX-2 inhibitors. Preloading with an oral dose on the day before surgery seems to help in achieving adequate pain control, and these drugs do not appear to worsen the incidence of hematomas. Instillation of 10 ml of plain 0.25% bupivacaine into the implant pocket before closure also provides early postoperative pain relief, as does the use of bupivacaine infusion pumps such as the OnQ or Stryker devices.

A soft bra without underwiring is used. Patients should not drive for at least 2 weeks postoperatively, and high-impact aerobic exercise is discouraged for 6 weeks. Implant massage may be helpful and certainly does not seem to cause harm; it can be started as soon as the patient is comfortable enough to massage the breasts. The use of leukotriene inhibitors such as zafirlukast (Accolate) is of debatable benefit but carries few side effects. Postoperative antibiotics are still used by most surgeons, although there are no hard data that their use is of any more value than that of perioperative antibiotics alone in limiting postoperative wound infections.

Outcomes

The results of breast augmentation are gratifying and provide patients with an immediate enhancement in breast size. The impact of this shape and volume change on the patient's psyche has been positively documented. Careful patient selection results in a highly satisfied patient population on the whole. Clinical outcomes in breast augmentation are highly satisfactory, with the exception of the occurrence of capsular contracture and implant leakage, both of which will be discussed later in this section. Early complications of primary breast augmentation, such as hematoma and infection, are exceptionally rare. Hematoma rates are reported at less than 4% in most series, and careful attention to intraoperative hemostasis should lower this to 1%. Infection is also extremely rare, and the use of perioperative antibiotics, antibiotic lavage of the implant pocket, and meticulous attention to technique with the incorporation of a no-touch technique have substantially reduced infection rates. Although implant and expander infection rates have ranged from 3% to 35% in reconstructive breast surgery, cosmetic augmentation mammoplasty infection rates should be less than 1% in experienced hands. The importance of meticulous operative technique has been emphasized repeatedly, not only for implant infection reduction but what is more important, for reducing capsular contracture, which is thought to be related to subclinical infection.

Capsular contracture undoubtedly remains the most frustrating and most common complication of breast augmentation. Numerous investigators have reported their experience with saline, gel, and smooth and textured devices, with markedly differing results. The Mentor and Allergan studies have helped clarify some of the data. Mentor reported an 8.3% risk in primary augmentation and a 16.3% risk in secondary augmentation. Allergan reported a 15% to 20% risk in both augmentation and reconstruction patients together. These figures remain high. From the plethora of retrospective and some prospective data available, several conclusions seem valid. Saline-filled implants are clearly associated with a reduction in capsular contracture rates in most reported studies. Polyurethane coating of gel-filled devices reduces capsular contracture to less than 1% during the first 10 years after surgery. In an effort to mimic the polyurethane surface by texturing of the gel implant wall, some reduction of capsular contracture occurs. Alternative fillers have been disappointing both in their rupture rates and their capsular contracture rates; hydrogel implants (polyvinylpyrrolidone [MISTI Gold]) and lipid-filled devices (Trilucent) failed to live up to expectations and were withdrawn from the market. Double-lumen saline-gel combination implants have had a good performance record, and texturing appears to further reduce their contracture rates. Although U.S. surgeons have limited access to cohesive gel implants, plastic surgeons elsewhere have had considerable experience and report positive results with the newer form-stable cohesive gel devices; however, accurate long-term follow-up data are still sparse. Capsular contracture is purportedly low, but patients often complain of breast stiffness because of the firmness

of the gel. The new generation of softer cohesive gels appears to have solved this problem. Implant position is still a significant factor in reducing capsular contracture. Partial submuscular placement does appear to reduce contracture rates, possibly because of the massaging effect of the pectoral muscles. A 58% incidence of capsular contracture has been noted when smooth silicone devices were placed in the subglandular position, compared with a 9% rate when implants were placed in the subpectoral plane; similar results were found with smooth saline implants.

To prevent capsule formation, steroids have been instilled intraoperatively into saline implants, with variable success. A reduction in capsular contracture has been reported with the use of 40 mg of methylprednisolone within a double-lumen prosthesis, whereas a higher incidence of erosion, skin atrophy, and ptosis has been demonstrated, despite a drop in capsular contracture rates, when steroids were instilled within the implant. This is not surprising, given that steroids are heavier than water and gravitate to the lower pole of the implant, thereby enabling diffusion to occur to the lower pole of the breast. Intraluminal steroid injection should not be performed, because steroids tend to settle inferiorly, and diffusion into the tissues can cause thinning of the lower pole of the breast, increasing the potential for extrusion. Systemic antibiotic prophylaxis, per se, has not been shown to affect contracture rates, but it has been shown that topical pocket lavage with a mixture of cephalosporin and gentamycin may positively affect contracture rates. Use of Mladick's no-touch technique also appears beneficial. Some consider postoperative breast compression helpful, and it carries the benefit of involving the patient in her own care. The value of oral vitamin E therapy is highly conjectural.

For treating established capsular contracture, the use of saline and textured implants may be helpful, whereas subglandular implants may be converted to the submuscular or biplanar location. The question of whether a total capsulectomy is preferable to an anterior capsulectomy remains unanswered. It has been shown that subglandular capsules should be totally removed, because an anterior capsulectomy alone tends to result in higher recurrence rates. Implant malposition remains a significant cause for reoperation at rates of 1.4% to 4.6% in primary augmentation and as high as 14.8% in secondary augmentation.

Concluding Thoughts

Implant-based breast augmentation is gaining in popularity once more and is an effective procedure for breast enhancement. There are more implant choices, both in filler materials and contours. Careful selection of the appropriately shaped device for a given breast morphology can produce stable, long-lasting results. These results depend on good surgical technique based on clear anatomic principles.

Clinical Caveats

Inframammary incisions should be placed below the inframammary fold, because they tend to rise up onto the breast mound as skin is recruited from below.

Overdissection should not be done in any direction; the pocket size and location should be created to place the implant exactly where it is wanted.

Overdissection through the pectoralis major muscle medially, as well as dissection into the subcutaneous fat, may increase the propensity for ripples and wrinkles to appear, whereas inferomedial overdissection produces a boxy breast deformity.

The cavity should never be washed with Betadine solution.

When using endoscopic equipment, the camera orientation should be checked to prevent inadvertent thoracic penetration.

To prevent cutaneous burns, endoscopic cautery insulation should be checked before it is used.

The no-touch technique is used whenever possible to reduce implant contamination.

Extremely large implants should be avoided, because implant volumes of more than 400 cc tend to be associated with higher complication rates.

Annotated Bibliography

Adams WP Jr, Rios JL, Smith SJ. Enhancing patient outcomes in aesthetic and reconstructive breast surgery using triple antibiotic breast irrigation: six-year prospective clinical study. *Plast Reconstr Surg* 117:30-36, 2006.

This landmark paper reviews the 6-year prospective data highlighting the value of triple antibiotic irrigation in reducing capsular contracture after implant surgery. It emphasizes the likely role of subclinical bacterial contamination in the generation of capsular contracture.

Cronin TD, Gerow FJ. Augmentation mammoplasty: a new “natural feel” prosthesis. *Transactions of the Third International Congress of Plastic Surgery, Washington, DC, 1963*, pp 41-49.

A historically important paper in which the authors presented their initial experience with the “new” gel-filled prosthesis, a major breakthrough for breast augmentation as well as breast reconstruction.

Hester TR Jr, Nahai F, Bostwick J III, et al. A 5-year experience with polyurethane-covered mammary prostheses for treatment of capsular contracture, primary augmentation mammoplasty, and breast reconstruction. *Clin Plast Surg* 15:569-585, 1988.

The authors presented the Emory University 5-year experience with these outstanding implants. Polyurethane-coated devices revolutionized the approach to capsular contracture and paved the way for the current generation of silicone-textured saline- and gel-filled implants.

Mladick R. "No-touch" submuscular saline breast augmentation technique. *Aesthetic Plast Surg* 17:183-192, 1993.

The importance of the no-touch approach in an effort to reduce implant contamination as a means of reducing capsular contracture is emphasized. The author's minimal incidence of this complication suggests that more attention should be paid to this technique.

Price CI, Eaves FF III, Nahai F, et al. Endoscopic transaxillary subpectoral breast augmentation. *Plast Reconstr Surg* 94:612-619, 1994.

The first description of endoscopic breast augmentation; the technique used the transaxillary approach and helped to resurrect this approach for routine augmentation. This article led to further advances in endoscopic augmentation and attempts at endoscopic capsulotomy and made developments in endoscopic lumpectomy and latissimus breast reconstruction possible.

Tebbetts JB. Dual plane breast augmentation: optimizing implant-soft-tissue relationships in a wide range of breast types. *Plast Reconstr Surg* 107:1255-1272, 2001.

The author brings his vast experience to the concept of dual-plane augmentation, emphasizing the important relationship of implant position to that of the overlying breast in an effort to improve the final shape of the augmented breast.

CHAPTER 63

Fat Grafting to the Breast

EMMANUEL DELAY, MICHEL MOUTRAN

Transferring fat from body areas where it is present in excess (as in the abdomen and thighs) to the breast for cosmetic and aesthetic purposes is not a new concept. This approach has been considered since the very beginning of liposuction, particularly after publications by Illouz and Fournier. However, the concept remained controversial and did not become widely used until the development of more precise tools and techniques. It was feared that autologous fat transfer would generate fat necrosis and calcifications that at that time could not be readily assessed because of the limitations of available imaging modalities.

Fat grafting regained popularity after the confirmation by Coleman that fat tissue can be transplanted safely if meticulous care is exercised in the preparation and transfer of fat cells. Coleman's preliminary work was mainly on facial rejuvenation. In 1998, given the proven efficacy of fat transfer to the face for facial rejuvenation or postsurgery reconstruction, we developed a research program to evaluate the efficacy and safety of the procedure for thoracomammary reconstruction. We adapted the technique for breast procedures and named it *lipomodeling*. We assessed its efficacy and tolerance in patients and demonstrated an absence of significant clinical or radiologic signs of adverse effects.

In this chapter we present the evolution of ideas and the progress of knowledge about fat grafting to the breast, describe its indications and contraindications, and highlight its advantages and disadvantages. We also present some of our results obtained with this promising technique.

Evolution of Technique

First Attempts

Fat grafting for breast plastic surgery has long been advocated by prominent surgeons. In 1895 Czerny described the first clinical case of breast reconstruction by transplantation of a giant lipoma of the buttock region to the left breast. Adipose cells were used to fill the void left in the breast after tumor resection in a patient with a fibroadenoma. Some investigators performed breast reconstruction or augmentation using fasciocutaneous flaps, gluteous fat implants, or local pedicled flaps. Others have injected fat either directly into the breast or into previously inserted implants. Some have even reported the cases of women undergoing augmentation mammoplasty with cadaver fat allografts. However, tolerance of fat allografts is poor, and all of these grafts had to be removed eventually because of inflammatory reactions, sometimes after several years. In 1991 Fournier described the fat grafting technique he used in patients who did not want a prosthesis and who requested only moderate breast augmentation. The quantity of fat grafted to these patients was between 100 and 250 cc, injected in the retroglandular space, not in the mammary parenchyma.

The Controversy

Fat grafting to the breasts has been highly controversial since the presentation by Bircoll, first in Bangkok in 1984, then at the California Society of Plastic Surgeons in 1985, of a patient undergoing breast augmentation by injection of fat cells obtained by liposuction. The patient was a 20-year-old woman who requested a moderate augmentation of her breasts while undergoing fat grafting to repair the damage caused by a dog bite. Bircoll and Novack considered that the technique should only be used for women requesting moderate augmentation because of the potential risk of necrosis when large quantities of fat were grafted. In 1987 Bircoll reported the principal advantages of the procedure: its simplicity, the absence of a scar, and rapid recovery. In addition, a prosthesis was not necessary and thus prosthesis-related complications were avoided. He also noted the positive slimming effects at the harvest site. Bircoll and Novack reported the case of a patient undergoing bilateral fat grafting after unilateral reconstruction by TRAM flap; the fat grafting improved the aesthetic results and symmetry. The two papers triggered reactions from the medical community; many expressed strong disapproval, citing the possibility that autologous fat injections in the breasts could generate microcalcifications and cysts that could potentially interfere with the detection of early breast carcinoma. Bircoll argued that cancer-related calcifications and those following fat transplantation occur in different sites and have different radiologic aspects and therefore cannot be mistaken, and further, that breast reduction surgery also results in microcalcifications. But in 1987, the Ad-Hoc Committee on New Procedures of the American Society of Plastic and Reconstructive Surgeons issued a position paper that stated, "The committee is unanimous in deploring the use of autologous fat injection in breast augmentation," and further, that "much of the injected fat will not survive, and the known physiologic response to necrosis of this tissue is scarring and calcification. As a result, detection of early breast carcinoma through xerography and mammography will become difficult and the presence of disease may go undiscovered."

There was no reference in the paper to scientific findings, and the report expressed only the opinion of the members of the committee. Despite the paucity of scientific information, and although it had long been recognized that any mammary surgery can cause oily cysts or mammographic changes, the injection of fat into the breasts became taboo among surgeons, limiting research and experimentation on this topic.

Ironically, in the same journal in 1987, Brown et al published a retrospective study of mammographic changes after breast reduction, reporting that calcifications were detectable in 50% of all mammograms at 2 years after surgery. The authors insisted that in most cases these benign calcifications were easily distinguishable from changes associated with cancer. Despite this high incidence of calcifications and the risk that mammographic abnormalities might interfere with cancer detection, there was no subsequent discussion of discontinuing breast reduction mammoplasties on the basis that such a procedure might interfere with breast cancer detection.

Lifting the Taboo

Fat grafting had proved very efficient for facial rejuvenation and for the correction of facial deformities. Thus in 1998 we focused our research on the subject and adapted the technique to breast reconstruction. First, we used fat grafting in conjunction with autologous latissimus dorsi flap reconstruction. This flap reconstruction, previously developed by our surgical unit, allowed satisfactory reconstruction in 70% of cases, but the other 30% resulted in insufficient breast volume. Reduction of the contralateral breast was needed, or else a prosthesis had to be inserted, which was precisely what we wanted to avoid in the first place, because the procedure would no longer be autologous and because of the drawbacks associated with prostheses (unnatural shape and texture and the need to replace the prosthesis at some point).

We started using fat grafting in patients undergoing autologous latissimus dorsi flap reconstruction who were at low risk of local recurrence. We named the technique *lipomodeling*, from the Greek root *lipo* for “fat,” and the Latin *modello*, “to give shape or volume,” which is exactly the objective of this procedure. At first we used the fat grafting technique only on 20 volunteer patients who agreed to undergo strict initial follow-up for 1 year. After the efficacy of the technique had been demonstrated, with results yielding optimal shape and texture as well as a natural décolleté, we proposed lipomodeling to almost all patients treated by latissimus dorsi flap reconstruction. The study of mammography, CT scan, and MRI findings conducted on patients in parallel demonstrated that fat grafting did not interfere with our ability to perform imaging studies on the patients. It was thus progressively extended to other indications of breast reconstruction, then to the correction of breast deformities, and finally to the treatment of sequelae of conservative treatments. Our first presentations at the Société Française de Chirurgie Plastique Reconstructrice et Esthétique and the International Confederation for Plastic Reconstructive and Aesthetic Surgery raised considerable controversy, of the same order as the criticisms made in 1987. Point-by-point debate gradually overcame the skepticism of the clinical community, and fat grafting has now become a standard procedure in breast reconstruction.

Indications

Lipomodeling of the breast and chest wall has many indications. It has been of great benefit in reconstructive breast surgery. In aesthetic breast surgery and in selected cases, fat transfer precludes the need for an implant (augmentation, and mastopexy with a slight lack of fullness in the upper pole). It can also efficiently correct certain defects of implant augmentation. Fat grafting has become a standard and useful procedure for enhancing the outcomes of breast aesthetic surgery.

Patient Profiles

Poland's Syndrome

Correction of the deformities of the breast and thorax associated with Poland's syndrome remains a daunting challenge. Lipomodeling appears to be very effective in these cases. Breast rehabilitation with fat grafting only leads to excellent outcomes with simple but repeated procedures, resulting in very limited scarring and donor site morbidity. We have treated 16 patients with different severities of Poland's syndrome, among them 14 requiring lipomodeling alone and 2 treated with a combination of lipomodeling and pedicle flap reconstruction. In this series, three sessions, on average, were required to obtain the desired result, with a mean of 244 cc injected during each session. The results were notable: it was possible to restore the breast, giving it a shape almost identical to that of the contralateral breast. The introduction of this technique appears to be a major breakthrough for the management of thorax and breast deformities in patients with Poland's syndrome.

Pectus Excavatum

Pectus excavatum is a complex deformity with hollowing of the anterior sternocostal wall; it usually has little or no impact on respiratory function. Most patients are principally concerned about structure and aesthetics when there is significant deformity of the breast, especially in severe or lateralized pectus excavatum. Fat transfer techniques can be used alone to produce satisfactory correction for mild to moderate forms, or in association with a custom-made rigid implant (based on three-dimensional CT images) for more severe forms.

Tuberous Breasts

Tuberous breast deformity is an uncommon breast anomaly in which there is a constriction in the lower pole of the breast. It becomes apparent at puberty with the growth of the breast. Various surgical approaches have been described, and a wide range of techniques are available to produce an optimal result. Among them, lipomodeling can correct the lack of volume (especially if this is unilateral) and improve the base and shape of the breast. It is a very useful adjunct in the treatment of tuberous breasts. Recently Coleman reported encouraging results in patients with tuberous breast deformity treated by fat injection.

The ideal indication is a unilateral hypoplastic tuberous breast (which usually requires two fat transfer sessions) associated with a lack of fullness of the upper pole. In cases of bilateral breast hypoplasia associated with tuberous deformity, implants remain the standard treatment, unless the condition is associated with sufficient lower body adiposity to augment the two breasts satisfactorily. Lipomodeling can significantly enhance the results of these corrections by improving the décolleté area.

Asymmetrical Breasts

Asymmetry is a difficult problem when one breast has satisfactory fullness and perfect shape and the other is hypoplastic. Conventionally, augmentation with an implant in the underdeveloped breast is the standard treatment. Although the initial results of this approach are generally satisfactory, asymmetry of shape and volume often reappears several years later. In this indication, lipomodeling yields a breast

very similar to the normal breast, and the change over time is natural, particularly in regard to ptosis. Depending on the degree of asymmetry and hypoplasia, one to three fat transfer sessions will be needed for an optimal result.

Bilateral Breast Augmentation

Lipomodeling in aesthetic surgery is developing rapidly. Our studies have shown that if lipomodeling is carried out according to the technique we describe in this chapter, it does not generate radiologic images that raise problems of differential diagnosis with breast malignancy or problems of radiologic follow-up for radiologists who specialize in breast imaging.

The main radiologic risk is that breast cancer may occur coincident with lipomodeling. To reduce this risk, imaging studies (mammography and ultrasonography) are carried out before lipomodeling by a specialized radiologist to confirm the absence of any suspicious lesions. If there is any doubt, lipomodeling is deferred or contraindicated. The radiologist must concur before lipomodeling is performed and thereby becomes co-responsible for the follow-up. The patient gives written consent to undergo the same studies by the same radiologist 1 year after the procedure. If the radiologist observes a suspicious lesion on imaging at 1 year, a micro biopsy is performed to establish a definitive diagnosis. In this indication, the information given to the patient must be particularly thorough and extensive, with comprehensive handouts provided during the preoperative consultations.

The indications for breast augmentation with fat grafting (*lipoaugmentation*) differ from those of implant augmentations. Lipoaugmentation is suitable for patients requesting a moderate or even slight increase of breast volume or who want to recover the upper pole fullness they had before weight loss or pregnancy. The ideal patient is a young woman with a slim upper body and moderately small breasts who has sufficient localized adiposity of the lower body to allow one or even two lipomodeling sessions. In such a patient, fat harvesting should enhance the lower body contour and can be combined with standard liposuction to improve the final result. We encourage the patient to maintain a stable weight after this procedure, because any change in weight might affect the shape of the breasts.

Revision After Implant Augmentation

Aesthetic lipomodeling is a treatment option for correction of the imperfections of implant augmentation. It enhances the cleavage and décolleté area; improves tissue coverage of the implant, especially in the lower pole; reduces rippling in thin patients; and reduces the demarcation of the implant in the upper pole. We also have the clinical impression, though no scientific data as yet, that complementary fat grafting might improve capsular contractures in moderate cases. We usually recommend fat transfer with the previous implant still in place. After all deformities are corrected, the implant is replaced; this avoids any risk of leaving a punctured implant.

Managing Severe Complications of Breast Aesthetic Surgery With Residual Sequelae

Breast reduction, breast augmentation, and mastopexy are commonly performed procedures in aesthetic breast surgery. The outcomes are usually satisfactory for the patient and surgeon. In rare cases, complications occur. In thin patients who smoke, exposure of an implant can result in the need to remove the implant. Reduction of large breasts can result in fat and skin necrosis with subsequent breast deformity.

Some patients are referred to our clinic for revision and secondary procedures. We find lipomodeling to be very useful in these cases. It efficiently enhances tissues thickness and improves tissue quality.

After implant complications leading to implant removal, lipomodeling prepares the tissues to render the secondary augmentation safer. After complicated breast reductions, fat transfer can restore the suppleness of the breast while improving the quality of the damaged skin.

These complementary fat grafting procedures have reduced donor site morbidity while reducing the incidence of breast sequelae. We have also found lipomodeling to be very useful in the management of difficult patients with high expectations who may present a risk of medicolegal issues.

Preoperative Assessment

The patient's weight should be stable at the time of the procedure, because the injected fat will retain the characteristics of the fat deposits in the donor site. If the patient loses weight after lipomodeling, she will lose some of the benefits of the procedure.

The operative technique, its benefits, and potential risks and complications are thoroughly discussed with the patient, and she is provided with an informational handout with an informed consent to sign. We have four handouts: lipomodeling in breast reconstruction, lipomodeling to correct the sequelae of conservative treatment, lipomodeling to correct breast deformities, and aesthetic breast lipomodeling.

Preoperative Planning

Markings

The areas of the breast that require correction are identified and marked on the patient. In some patients we now perform a three-dimensional morphologic study, in addition to the usual two-dimensional photographs; this provides further useful information for assessing the amount of fatty tissue to be transferred and evaluating secondary fat resorption.

The various adipose areas of the body are examined to identify excess fat deposits. Generally, we harvest fat from the abdomen, because harvesting in this area does not require a change in the patient's position during the procedure, and liposuction in the region can lead to beneficial recontouring. The second site is the trochanteric region (saddlebags) and the inside of the thighs and knees. The areas to be harvested are outlined with a skin marker.

Operative Technique

Anesthesia

Because of the significant amounts of fat harvested, lipomodeling is performed with the patient under general anesthesia in most cases. Conventional prophylactic antibiotics are usually given perioperatively, as we customarily do in various plastic surgery procedures. Local anesthesia can be used for minor revisions to correct any residual defect.

Incision Placement

In the harvest sites, incisions are made with a No. 15 blade. For abdominal harvesting, four incisions are made around the umbilicus, and a lateral incision is made on each side if lateral abdominal and suprailiac fat is to be harvested. For harvesting from the thighs, the patient is placed in a ventral decubitus position, and an incision is made in each subgluteal fold. A complementary incision on the inside of the knees can be made for fat harvesting of this area.

At the recipient site on the breast, punctiform incisions are done with a 14-gauge needle; it is ideal to hide these sites in previous scars. To create a network of transfer tunnels, five or six incisions are needed, two of which are in the inframammary fold and one in the décolleté area. The incisions are usually made with the sharp bevel of a trocar.

Fat Harvesting

Recent published studies on fat transfer have contributed to standardization of the procedure for harvesting and injection, thus reducing the potential pitfalls at each stage. Meticulous technique throughout the process enhance fat survival in the short, medium, and long term. A disposable or Coleman cannula is used for harvesting. These cannulas have a blunt tip that can be inserted in a 4 mm incision made with an No. 15 blade. Harvesting is done with a syringe. Subcutaneous infiltration is done with 500 ml of a 9% normal saline solution and 0.5 mg of epinephrine. A 10 cc Luer-Lok syringe is fitted directly onto the harvesting cannula.

Moderate suction will minimize damage to the fat cells; mechanical suction that is too strong might have a harmful effect on adipocyte survival. More fat than has been calculated for transfer must be harvested in anticipation of the separation resulting from centrifugation and the expected resorption of fat in the breast after transfer.

Finally, to perfect the morphologic result, the harvested areas are smoothed with conventional liposuction using a 4 mm cannula. The cutaneous incisions are closed with fine, rapid-absorbing sutures.

Fat Preparation

As harvesting continues, the assistant prepares the syringes for centrifugation. They are sealed with a screw top and then centrifuged in batches of six for 1 minute at 3200 rpm. Centrifugation separates the harvested fat into three layers: a top layer of oily fluid containing chylomicrons and triglycerides resulting from cell lysis; a lower layer of blood, debris, and serum, as well as the infiltration fluid, especially if the harvesting is done with a local anesthetic; and a middle layer of purified fat. This is the useful layer that will be injected.

The other two layers are disposed of, the lower layer simply by removing the cap and the upper layer by pouring off the oil the covers the middle layer. The team must be well organized so that fat preparation is carried out efficiently and rapidly. With a three-way tap, the purified lipoaspirate is grouped into 10 cc syringes by transfer from one syringe to another, thus producing a sufficient quantity of 10 cc syringes of purified fat.

Fat Transfer

After the fat has been prepared, the 10 cc syringes of fat are ready for transfer. The fat is transferred directly to the breast areas with the 10 cc syringes fitted with special disposable 2 mm transfer cannulas. These cannulas are longer and stronger than the cannulas used for facial fat grafting procedures, because the recipient breast tissue is firmer and more fibrous. The incisions are made using a 17-gauge trocar. This produces an adequate incision while limiting scarring. Several incisions are made to create a honeycomb of multiple microtunnels for fat transfer.

The fat is injected in 1.5 to 2 cc per pass in the form of fine cylinders resembling spaghetti. Microtunnels must be created in many directions. Transfer is done from the deep to the superficial layer. Good spatial visualization is necessary to form a three-dimensional matrix and to avoid areas of fatty collections that would lead to fat necrosis. Each microtunnel must be designed to be surrounded by well-vascularized tissue. *Fat is injected under light pressure as the cannula is gently withdrawn, not during advancement of the cannula.*

As noted, one must overestimate the quantity of fat transferred when possible, anticipating a 30% expected fat resorption. A 140% rule must be applied, meaning that 140 cc of fat must be injected for a desired final volume of 100 cc.

When the recipient tissues are saturated and cannot absorb more fat, it is useless to persist because of the risk of inducing areas of fat necrosis. *Oversaturation of the recipient site with fat grafts must be avoided.* Planning a supplementary session in a few months is preferable and leads to more stable results. Very fine, rapid-absorbing sutures are placed, and the breast is covered with an ordinary dry dressing for a few days.

Ancillary Procedures to Improve Results

Liposuction of the Inframammary Fold

In patients with a bulky inframammary area anterior to the inferior ribs, we perform a heavy liposuction of the area (7 to 8 cm under the inframammary fold). This liposuction enhances the projection of the breast and lends inframammary definition while giving the impression of a complementary breast augmentation.

We use this method in major breast reduction procedures in overweight patients to improve the definition of the breast. It can also be used in tuberous breasts and in lipomodeling-only breast augmentation to improve the final outcome.

The technique consists of significant liposuction, going from the deep to the superficial layers of the skin in the predefined area while restoring the inverted V resulting from the junction of the two inframammary folds and the intermammary valley. Because liposuction in this area is painful, we infiltrate dilute ropivacaine at the end of the procedure.

Inframammary Fold Definition

In some cases of aesthetic breast surgery, the inframammary fold is ill defined or has been damaged by previous surgery. A push-up bra will enhance the fullness of the upper pole by displacing the mammary gland to the upper region, simultaneously displacing the necessary amount of tissue to define the inframammary fold from the lower pole.

We consider the inframammary fold to be the foundation of the breast. To create or re-create the inframammary fold (see p. 2303), we use a technique derived from our reconstructive experience in cases of latissimus dorsi reconstruction with a low-situated inframammary fold.

We locate the desired level of the inframammary fold and draw a horizontal marking on the midclavicular line. We mark a horizontal ellipse under this desired inframammary fold (5 to 6 cm wide and 2 to 3 cm high). The ellipse is deepithelialized and the upper border of the ellipse is incised to the thoracic wall with cautery.

The deepithelialized flap is kept attached to the thoracic skin while the deep plane is undermined for 5 to 6 cm. This deepithelialized flap is pulled up under the breast and sutured to the thoracic wall with 1 Vicryl at the predefined position of the inframammary fold. The lower pole of the breast is undermined at the level of the pectoralis muscle, then rolled to define the lower pole contour and sutured to the fixed inframammary fold.

The disadvantage of this technique is the resulting 6 cm scar, but this can usually be hidden in the inframammary fold. The main advantage is the enhancement and efficient correction of the inframammary fold.

In the rare cases in which this technique is used for lipomodeling augmentation of the breast, we start by fixating the inframammary fold, then we do the fat transfer.

Release of Fibrous Strings and Adhesions

While transferring fat to the breasts, the surgeon sometimes encounters fibrous strings or adhesion areas, making lipomodeling difficult. The inferomedial area in tuberous breasts is a typical example. In such cases we recommend the use of V-shaped transfer cannulas or the tip of a 14-gauge trocar to selectively rupture these strings and adhesions under local tension. Care must be taken not to undermine the area, because the transferred fat will not take if it is not in proper contact with a vascular recipient site.

External Expansion of the Breast

External expansion of the breast with the Brava breast enhancement and shaping system (Brava, Coconut Grove, FL) was developed by Roger Khouri in the 1990s for breast augmentation without surgery. A gentle three-dimensional vacuum is applied via two silicone domes that place the breast under tension. The expected outcome is breast tissue augmentation, given strict adherence to the protocol, which means that the device must be worn 10 hours a day for 10 weeks. The use of the system alone did not lead to significant volume enhancement because of the constraint of wearing the Brava bra daily for an extended time.

With the recent development of fat grafting to the breasts, Dr. Khouri decided to combine fat grafting with the Brava system. The external expansion is used for the preparation and optimization of the recipient site. The concept behind this is to increase the initial breast volume so larger amounts of fat can be transferred to the breasts. External tissue expansion might also enhance the vascular supply to the breast and thus improve graft take.

At present, we are evaluating the Brava system in conjunction with our lipomodeling procedures. Our preliminary experience shows that we are able to transfer larger amounts of fat in one lipomodeling session as compared with the traditional tech-

nique. Our second impression is that there is improvement in areolar projection with the combined use of the Brava system and lipomodeling.

The external expansion system might change the surgical indications in cases of severe Poland's syndrome and breast reconstruction with fat transfer only. It might even eliminate the need for flap reconstruction in some cases. A study is underway in our department to determine more precisely the advantages of the Brava system and its indications.

Processed Fat Grafting With Enrichment Procedures

Fatty tissue is rich in adipose-derived stem cells at different levels of differentiation with multiple progenitors. It has been proposed to modify the composition of the fat transferred by enriching it with adipose-derived stem cells. The protocol consists of harvesting the fat, then processing it in the Celution system (Celution System, San Diego, CA), which will release concentrated stromal cells. These stromal cells are mixed with the fat harvested before its transfer to improve the take of the graft. Studies are underway in Europe and Asia to determine the efficacy of this system. At present the system has not yet obtained FDA approval in the United States or AFSAPS approval in France.

Postoperative Care

Harvest Sites

Pain in the harvested areas is similar to the pain after liposuction. Patients complain of moderate pain that typically lasts 48 hours; this can be treated with level 1 analgesics, prescribed for 2 weeks. We infiltrate dilute ropivacaine at the end of harvesting to control pain during the first 24 hours. At the end of the procedure, a compressive elastic dressing is left in place for 5 days.

Considerable bruising occurs in the harvest sites and persists for 2 weeks. Postoperative edema resolves totally or almost totally in 3 months. To hasten resorption, we ask patients to massage the harvest sites with a circular motion. An abdominal support belt may be advisable for 6 weeks but is not prescribed routinely. In rare cases, if edema persists, we advise 10 sessions of endermologie drainage.

Breast

Bruising resolves in 2 weeks, edema in 1 month. During the first 3 postoperative months, 30% to 40% of the added volume is gradually lost. But because of the initial edema, the patient may have the impression that she has lost about 50% of her breast volume, because she saw the breast the day after the procedure, when the breast was the most swollen.

Complications

At the harvest site, scars must be concealed as much as possible, generally in a fold or in the periumbilical region. No patients have complained of unaesthetic scars in a donor site. We had one case of irregularity in the suprailiac region that required secondary correction by lipomodeling. The majority of patients are satisfied with the slimming of the donor site; this additional benefit probably contributes to the very high rate of satisfaction with this technique. Irregularities at the donor site may be caused by uneven harvesting of the fat grafts, so harvesting is sometimes completed by liposuction to further improve the result and for greater patient satisfaction.

This procedure must be carried out by experienced plastic surgeons who have completed their learning curve, because previous experience with cosmetic liposuction is essential in these circumstances to limit the risk of complications and to produce the best possible cosmetic result.

Local infection occurred in only 1 of our 950 lipomodeling procedures. This was seen as redness around the umbilicus and was treated with antibiotics and local application of ice, with no long-term sequelae.

In the breast the incisions must be well placed, in the submammary fold or in its axillary tail, or in the areolar region, where scars are always of good quality. The presteral area should be avoided because there is an increased risk of hypertrophic scarring, seen as small, red, hypertrophic, punctate scars. The incisions are usually invisible: because they are made with a trocar, they measure only 1.5 mm.

Infections occurred at the recipient site in 6 of our 950 lipomodeling patients. Redness at the recipient site was seen, and sutures were removed. An effusion of fat and pus was evacuated. Topical treatment, antibiotics, and applications of ice completely resolved the problem in each case, with no impact on the final results.

We had one case of intraoperative pneumothorax in 950 procedures, probably as a result of the transfer cannula piercing the pleura. The pneumothorax was revealed by oxygen desaturation during the procedure. In the recovery room, a pleural drain was inserted, and oxygen saturation returned to normal, with total recovery and no sequelae. To avoid this complication, the projection of the areolar region should be improved through two incisions in the submammary fold, not through the areolar region itself.

There were no instances of fat embolism in our series. There is a potential risk of this if fat is injected into a large vessel. Extreme caution is recommended in the subclavian area, especially in the breast and chest wall deformities of Poland's syndrome, where the subclavian vessels may lie lower than in a patient with normal anatomy.

In 3% of cases we observed focal fat necrosis. The risk is higher during a surgeon's early experience (15% in the first 50 cases). In these cases, fat necrosis occurred in areas overtreated and oversaturated with fat; the recipient site could not absorb the amount of fat grafted. When the recipient tissue is saturated with fat, the surgeon should not persist, because areas of fat necrosis may develop. Clinical signs of fat necrosis are typical: tender, slightly sensitive but stable over time, then gradually decreasing. *Any increase in the size of a hard swelling, even in a reconstructed breast, should signal the need for microbiopsy by a radiologist to rule out a malignant change.*

Fat necrosis nodules are mainly seen in the early stages of the surgeon's learning curve and decrease as experience increases, if he or she respects the principle of the three-dimensional injection network and avoids oversaturation of the recipient site.

Outcomes and Long-Term Follow-Up

Based on the first author's (E.D.) personal experience of 880 procedures of reconstructive and aesthetic breast surgery, and with a 10-year follow-up for the first patients, reliable indications on long-term follow-up can be stated.

Clinical

All patients were clinically followed and seen in consultation after 15 days, 3 months, and 1 year. Photographs were taken at each visit. A detailed follow-up protocol was used to assess the quality of the result from the patient's and surgeon's viewpoint, to document patient satisfaction, and to note any adverse effects or complications.

The results were considered very good or good in the majority of cases. Very few results were considered to be moderately good, and none was evaluated as poor. The percentage of good or very good results depends on the subpopulation studied in relation to the indications. For example, for correction by lipomodeling of sequelae of breast-conserving therapy, 50% were considered very good, 40% good, and 10% moderately good.

Patients who had had breast cancer and underwent a lipomodeling procedure after breast-conserving therapy or breast reconstruction were then followed by their oncologist, who referred them to us if there was any change in the follow-up clinical and imaging findings. For the other patients, computerized medical records were shared among the radiologist, oncologist, breast surgeons, and plastic surgeons to complete the long-term follow-up.

Radiologic

In 1998, when we developed this area of research, the main fear concerning fat transfer in the breast was the risk that it would compromise imaging studies. This fear had in fact led to the earlier described controversy of 1987 and its consequences. For this reason, we undertook analysis of the effect of fat transfer on breast imaging. We carried out three studies with imaging of breasts reconstructed by autologous latissimus dorsi flaps and lipomodeling (mammography, ultrasonography, and MRI), imaging of breasts treated with breast-conserving surgery after lipomodeling (mammography, ultrasonography, and MRI), and imaging of breasts with defects corrected by lipomodeling (asymmetry, tuberous breasts, and Poland's syndrome) (in process).

Our findings showed that if lipomodeling is carried out according to modern standardized principles, it does not hinder correct breast imaging and follow-up. It is noteworthy that all procedures were performed by a surgical team that has completed its learning curve and with specialized radiologists who are familiar with the analysis of image findings potentially induced by fat transfer. These prerequisites are of fundamental importance for successful fat transfer in aesthetic breast surgery.

Imaging in the majority of reconstructed breasts yielded normal results, with some images of oily cysts and fat necrosis. Any abnormal findings observed indicated benign lesions, easily distinguished from suspicious lesions. Abnormal images were essentially oily cysts, occurring in 15% of cases.

The most complex situation concerned lipomodeling for the sequelae of conservative partial mastectomy. In this population fat necrosis develops in about 20% of patients postoperatively; lipomodeling doubles this incidence, generating mainly oily cysts but sometimes more complex lesions of fat necrosis.

Because of the spontaneous local carcinoma recurrence rate of 1.5% per year, follow-up must be rigorous. We believe that this indication should be restricted to multidisciplinary teams working with radiologists who have excellent mastery of the subject.

Oncologic

Ten years of oncologic follow-up have not revealed an increased risk of local recurrence after mastectomy or after conservative treatment. In fact, the clinical impression seems to be to the contrary. But to confirm this clinical impression, more-complex oncologic studies must be performed that match treated populations with reference populations with the same oncologic status.

Evaluation of the Success Rate

Clinical Evaluation

The success rate of fat transfer is easy to evaluate by clinical examination, the patient's opinion, and comparison of the photographs taken at each consultation with earlier photographs. Of the volume initially obtained through fat transfer, 30% to 40% is gradually lost. Volume is stable after 3 to 4 months and remains so if the patient maintains her weight. If the harvested fat is very oily (retains a very high percentage of oil after centrifugation), resorption may be higher (up to 40% to 50%) and may continue over a longer period (5 to 6 months).

If the patient loses weight, the volume of the transferred fat decreases, and the result is a smaller breast with possible asymmetry. Therefore it is important for the patient to understand that she must maintain a stable weight. Inversely, if she gains weight, breast volume increases.

When a second fat transfer session is performed to produce sufficient volume, resorption seems to be less, between 20% and 30%.

Very long-term evaluation (5 to 6 years) confirms that breast volume remains stable. If asymmetry appears after weight loss or gain (for example, after discontinuation of antihormonal treatments in adjuvant therapy for breast cancer), a complementary lipomodeling session can easily be performed. This technique offers flexibility and precision for a long-lasting revision that is appreciated by the patients.

Evaluation by Interferometry

Using three-dimensional interferometry technology, we studied changes in breasts over time after lipomodeling. The technique consists of light projection and reflection over three-dimensional structures (in this case, the fat grafted breasts). The reflected light is processed using modeling algorithms. This produces a three-dimensional representation of the breasts from which measurement of distance and volumes can be calculated. By comparing the models of the breast, breast volume can be accurately studied and the quantity of fat remaining after resorption can be assessed. This study confirmed our clinical impression: the rate of fat absorption at 3 months was estimated to be 30% to 40%. It also confirmed that volume remains stable after this period if the patient maintains a constant weight.

Results

This 17-year-old patient with Poland's syndrome was treated with two sessions of lipomodeling (205 cc, 297 cc) at an interval of 6 months. She is shown 1 year after the second procedure.

This 17-year-old patient with lateralized pectus excavatum was treated with two lipomodeling sessions of the right breast (200 cc, 360 cc). She is shown 1 year after the second procedure.

This 27-year-old patient with tuberous breasts was treated with two lipomodeling sessions of the left breast (209 cc, 179 cc), and right mastopexy and lipomodeling (100 cc). Her result 30 months after the second procedure is shown. The patient had a pregnancy before the final result without affecting the results.

This 22-year-old woman had marked asymmetry (unilateral hypoplasia). She was treated with one lipomodeling session of the left breast (250 cc). One year after the procedure, she is shown with improved symmetry and correction of her hypoplasia.

This 38-year-old woman had bilateral breast augmentation with one lipomodeling session (left breast 235 cc, right breast 220 cc). She is shown 15 days and 1 year postoperatively.

This 48-year-old patient was seen as a secondary case with severe sequelae after failure of many breast implant augmentations, and further mastopexy. She was treated with one lipomodeling session (left breast 250 cc, right breast 280 cc) and inframammary fold fixation. The flap was marked, then incised and deepithelialized. Incision of the upper part of the flap is shown, and finally flap fixation to the thoracic wall. Three months after the procedure, the restored inframammary fold is evident; a second session of lipomodeling is scheduled.

Concluding Thoughts

Lipomodeling is a major development in reconstructive and aesthetic surgery of the breast; we consider it to be one of the major advances of the past 20 years. The technique is now well codified, and the associated complication rate is very low. Clinical long-term follow-up shows that the morphologic result regarding volume is stable 3 to 4 months after the procedure. The development of focal fat necrosis is strongly operator dependent, occurring in 15% of cases in the surgeon's early experience and becoming stable at 3% after more experience. The radiologic appearance of the breasts is usually normal, sometimes with images of fat necrosis seen as oily cysts, or more rarely, calcifications or complex cysts. None of these images is likely to be confused with a diagnosis of cancer for radiologists who are experienced in breast imaging. If there is the slightest doubt, the next step must always be micro-biopsy of the suspect area to obtain a definitive diagnosis. Oncologic follow-up (now 10 years for our first patients) shows no increased risk of local recurrence or of development of a new cancer.

Evaluation of the success rate by clinical examination and by interferometry shows that 30% to 40% of the injected fat is resorbed. The final volume is reached in 3 to 4 months and is stable over time if the patient maintains a constant weight. If a second fat transfer session is performed, resorption will be somewhat less, usually between 20% and 30%.

Because of the low complication rate, the very good results obtained, and the excellent acceptance of the technique by patients, lipomodeling has completely modified our indications in plastic, reconstructive, and aesthetic surgery of the breast.

The use of lipomodeling to correct deformities of the chest wall and breast is rapidly being adopted. For the treatment of Poland's syndrome, lipomodeling appears to represent a major advance and will probably revolutionize the treatment of severe cases, producing reconstruction of unequalled quality after fat transfer procedures with a simple postoperative course and little scarring. Lipomodeling can also correct the breast and chest wall deformities associated with some cases of lateral pectus excavatum and is a useful adjunct to custom-made implants for more severe forms of pectus excavatum. It is a promising alternative treatment for tuberous breasts and implant-free correction of asymmetry caused by unilateral hypoplasia.

Finally, the applications of lipomodeling will no doubt continue to develop in aesthetic surgery for the correction of inadequate mammoplasty, correction of defects or complications of implants, and in lipoaugmentation for patients desiring moderate, natural breast enhancement and who have sufficient adipose deposits. Preoperative and postoperative imaging by a radiologist who specializes in breast imaging is essential to limit the risk that a cancer may occur coincident with lipomodeling.

Clinical Caveats

Careful preoperative clinical and radiologic assessment and clearance for the procedure are essential before a fat transfer procedure.

Fat must be injected in a multilayered fashion, starting from the deep plane and moving to the superficial plane.

Fat must be injected in fine tunnels in a consistent fashion to avoid fat necrosis.

Fat transfer should be stopped at each injection site when the recipient site is saturated.

Resorption rates, the quality of the fat transferred, and characteristics of the recipient site must be taken into account in initially overcorrecting volumes to produce the desired contour and volume.

Annotated Bibliography

Bircoll M. Cosmetic breast augmentation utilizing autologous fat and liposuction techniques. *Plast Reconstr Surg* 79:267-271, 1987.

This was the first detailed presentation of fat transfer to the native breast, harvested with liposuction for augmentation purposes. This paper initiated the controversy about the safety of fat transfer in regard to cancer imaging and detection.

Coleman SR. Long-term survival of fat transplants: controlled demonstrations. *Aesthetic Plast Surg* 19:421-425, 1995.

The author presents a clinical study of the long-term survival of fat transferred to the face with the initial rate of resorption, then a stable result, compared with a noninjected area.

Delay E, Delaporte T, Sinna R. [Breast implant alternatives] *Ann Chir Plast Esthet* 50:652-672, 2005.

A review of the current alternatives to breast implants, mainly the autologous ones. Pedicle flaps and free flaps are presented. Fat grafting is described, and its indications in aesthetic breast contouring and augmentation are discussed.

Delay E, Garson S, Toussoun G, et al. Fat injection to the breast: techniques, results and indications based on 880 procedures over 10 years. *Aesthet Surg J* 29:360-376, 2009.

A single-operator, large retrospective study of fat injection to the breast in its different indications: reconstructive and aesthetic. Techniques, expected results, and the necessary follow-up of patients are discussed.

Delay E, Sinna R, Delaporte T, et al. Patient information before aesthetic lipomodeling (lipoaugmentation): a French plastic surgeon's perspective. *Aesthet Surg J* 29:386-395, 2009.

Precise information to be given to the patient before she undergoes breast lipoaugmentation. This article is intended to help plastic surgeons in writing their informed consent documents.

Gosset J, Guerin N, Toussoun G, Delaporte T, Delay E. [Radiological evaluation after lipomodeling for correction of breast conservative treatment sequelae] *Ann Chir Plast Esthet* 53:178-189, 2008.

A thorough description of the radiologic imaging of breasts treated with fat grafting with typical benign calcifications and cysts. Any doubts about the imaging must be addressed with a biopsy.

CHAPTER 64

Breast Augmentation With External Expansion and Megavolume Autologous Fat Grafting

ROGER K. KHOURI, DANIEL A. DEL VECCHIO

In aesthetic plastic surgery no topic stirs as much excitement, curiosity, and on-going controversy as fat grafting to the breasts. Despite the increased popularity of the procedure, many unanswered questions remain, and there is an unmet clinical need for standardization of the process and for understanding the physiology and true fate of transplanted fat. In 2009 the American Society of Plastic Surgeons (ASPS) modified their previous position against fat grafting to the breasts, thus paving the way for more investigation into this procedure. Today many surgeons realize that with optimal technique, fat grafts to the breast survive indefinitely, and further, that the radiographic arguments behind the previously imposed ban are no longer valid, so many investigators around the world have begun sharing their previously unpublished experience with fat grafting to the breast.

Fat grafting is a powerful tool for filling and reshaping body contours. When this technique is combined with external expansion, it offers a viable option for breast augmentation and treatment of breast asymmetries. The key to this technique is preparation of the breast with preexpansion, controlled low-pressure graft harvesting, and infiltration of autologous fat through multiple needle puncture sites, with diffuse grafting in a three-dimensional fanning-weave pattern.

In this chapter we describe our rationale for external breast expansion with the Brava expansion system combined with megavolume fat grafting based on our clinical experience with more than 100 breast augmentation procedures, which have produced consistent results comparable to those achieved with implant augmentation (as documented by MR imaging and three-dimensional volumetric determination). We provide information on indications and patient selection criteria and outline our techniques and the results that may be expected when this combined technique is used for breast augmentation.

Background

The Brava external tissue expander

The Brava bra (Brava, Coconut Grove, FL) was initially developed in the 1990s as an external soft tissue Ilizarov expander to enlarge the breast. The device consists of a pair of semirigid domes with a silicone gel rim cushion that interfaces with the skin; it is worn around the breasts like a bra. A small, concealed, battery-operated pump maintains a low negative pressure inside the domes that does not interrupt capillary flow and that imparts on the breast surface a constant gentle isotropic distraction force. Studies have shown that when the device is worn in an uninterrupted fashion for 10 to 12 hours per day, true and long-lasting breast augmentation ensues over a period of weeks to months.

Combining a regimen of Brava external expansion with structural fat grafting can predictably yield a 200 to 300 cc breast augmentation per grafting session. For adequate expansion it is recommended that the Brava domes be worn at least 10 to 12 hours per day for a minimum of 4 weeks. Although the smaller domes can be concealed under loose clothing, most women prefer to wear the bra at home and to sleep with it on. Adequate expansion is attained when the breasts are estimated to have enlarged threefold to fourfold in volume. The better the preoperative expansion, the more fat that can successfully be grafted, and thus the larger the augmentation.

Indications for External Expansion With Megavolume Fat Grafting

Women with excess fat in the lower body and a fat deficiency in the breasts are obvious candidates for external expansion combined with fat grafting to the breasts. However, some of the most impressive results are seen in very small-breasted women (less than 100 cc), in whom a 200 cc breast augmentation can make a real differ-

ence, compared with women who already have breasts of 500 cc or more. This procedure is reserved for an informed patient who understands the concept of fat grafting and accepts responsibility for her result by adhering to the expansion protocol.

The best candidates for this technique:

1. Have favorable anatomy (donor fat, breast anatomy)
2. Do not have active detectable breast cancer (although the test has poor specificity, we recommend a preoperative MRI as the most sensitive test for any breast abnormality)
3. Have realistic expectations (a cup size increase)
4. Are reliable (can comply with the Brava regimen)
5. Are nonsmokers (smoking is an absolute contraindication)

Patient Profiles

Women After Childbearing With Preexpanded Breasts

Anatomically speaking, an ideal patient for Brava preexpansion and megavolume fat grafting is a patient who has had one or more children, has breast deflation but not frank ptosis, and has an adequate amount of donor fat. Patients who have had children have already undergone one or more episodes of parenchymal expansion from engorgement with breast milk. Engorgement creates a natural stretching and loosening of the parenchymal ligaments. Although this may have occurred years before the Brava expansion, this prior stretching of breast tissues allows an easier, more rapid expansion when Brava is applied, given the same degree of negative pressure and time used.

Often the breast deflation seen in multiparous patients is low-grade ptosis or pseudoptosis. Patients with frank ptosis who require a breast lift can also benefit from external expansion, but the timing of the mastopexy surgery is best performed at the completion of the grafting process.

Women With Small Breasts

Thin patients with small breasts often do not want a major volume increase; therefore even thin patients may be candidates for Brava preexpansion with fat grafting, as long as realistic expectations are discussed preoperatively. Smaller breasts, even if doubled in volume, are still not very large.

Women With Small, Dense Breasts

Breasts with dense parenchyma will expand with more difficulty than the soft breasts of a multiparous woman. Patients with dense-parenchyma breasts must be coached effectively to increase the negative pressure on the domes to achieve adequate preoperative expansion. Often the dense parenchymal breast will expand more in some areas, such as the periareolar region, than in others. This can result in a double-bubble constriction deformity that must be released at the time of surgery.

After expansion, there is a step-off deformity at the breast-areolar junction as a result of the lower resistance of the areolar tissue compared with the breast tissue. The problem can be seen in this patient, who will require three-dimensional mesh release intraoperatively to address this deformity.

Women With Constricted or Tuberous Breasts

Constricted or tuberous breasts require aggressive expansion, and following this the constrictions can be released mechanically using the “Rigotomy” three-dimensional mesh release technique (see p. 2334).

Constricted breasts, before and after expansion (and before fat grafting)

This patient is shown before and after expansion with the Brava system; no fat grafting has been done yet. She will require aggressive release of the inferior mammary fold using a three-dimensional mesh release Rigotomy technique at the time of fat grafting. Postoperative expansion is also often required for constricted breasts.

Patient Evaluation

Similar to the regimen for breast augmentation with implants, we think it is important to obtain a baseline evaluation of the recipient breasts before any intervention is planned. Our routine protocol calls for a baseline MRI for all women requesting augmentation with fat grafting. In young women with dense breasts, this is the most sensitive test. It also provides a three-dimensional image analysis of the breasts that is unattainable with conventional biplanar mammography.

Patients should also be evaluated for associated medical conditions that might otherwise exclude them from safely undergoing a liposuction procedure. We believe this is the aspect of the intervention that probably produces higher morbidity than breast fat grafting. Smokers, with their impaired microcirculation, are not candidates for fat grafting. Potential fat donor sites are evaluated for their availability.

Patient Selection and Education

Compliance

There are two critical areas of compliance: the patient's tissue and the patient. The mechanical compliance of the breast tissue is an important consideration in effective preexpansion and fat grafting. A properly motivated patient is vital for the success of preexpansion, which in turn is vital for the success of the fat grafting procedure. The surgeon and patient must be equally committed to the preexpansion process to achieve a successful result.

No Expansion—No Surgery

Despite adequate screening for compliant behavior, some patients who initially intend to proceed with Brava preexpansion and grafting will simply fail to expand. In these patients, fat grafting is not performed until satisfactory expansion is obtained. It is far better to postpone a procedure after a failed expansion than it is to move forward and perform what may result in a failed operation. Without adequate preexpansion, the results of fat grafting to the breast may be limited to small graft volumes (100 cc or less) that do not exceed high interstitial pressures in the recipient site. In breast augmentation, such volumes are rarely adequate to achieve core tissue projection replacement. Therefore, if a surgeon performs grafting on a patient whose breasts have failed to expand, it is likely that repeat procedures will be necessary. Inevitably, this will be interpreted as a failure of the procedure, resulting in the need for repeat procedures, a dissatisfied patient, or both.

Classification of Breast Morphologies

Based on our experience with diverse breast types, we have developed a hierarchy of preoperative breast morphologies, as shown in the table.

Preoperative Classification of Brava Breast Morphology

Type	Description of Breasts	Sessions
I	Multiparous, soft	1
II	Nulliparous, dense	1-2
III	Constricted or tuberos	2
IV	Mastectomy, nonirradiated	1-4
V	Mastectomy, irradiated	3-5

This classification takes into account the compliance of the patient's parenchymal tissue and the starting volume of tissue available for expansion. With this information one can advise patients about the effort required for the expansion and the realistic number of sessions required to achieve the desired result.

Patient education is crucial in ensuring adequate compliance with the expansion regimen. We show the patients pictures of the expected expansion effect and explain that the more their breasts are expanded and the larger they are at the time of grafting, the more grafts we can inject and the larger their breasts will be. An educated, informed patient then becomes a full participant in achieving her result. We plan an office visit a week or so before surgery to confirm patient compliance and to ensure adequate expansion. On occasion, we have postponed the surgery to allow more expansion time.

We believe there is no substitute for sufficient preexpansion. Last minute "cramming" by the patient does not result in successful preparation. It is ultimately the responsibility of the surgeon to adequately select, educate, coach, and follow up with patients to ensure that optimal preexpansion is attained.

Preoperative Planning

Overview of Megavolume Fat Grafting

Conceptually, megavolume fat grafting can be compared with sowing seeds in a three-dimensional field. Four critical components need to be optimized to maximize the potential for producing a high-yield crop:

1. *Seeds*: Fat harvesting and processing
2. *The field*: Preparation of the recipient breast: this remains the main limiting factor
3. *Planting*: Grafting technique
4. *Nurturing the planted seed*: Care of the breast after grafting

Fat Harvesting and Processing

A vast amount of literature has been written on the preparation and harvesting of fat. Unfortunately, there is little that is definitive and not subject to dispute. We present our preferred techniques and biases.

Harvesting Pressure

While a standard liposuction machine can generate up to 1 atmosphere (atm) (760 mm Hg) of negative pressure, a 60 cc syringe connected to an inline manometer can also generate nearly 1 atm of negative pressure. The adipocyte is impartial to the source of negative pressure; it is the absolute pressure and not the source of this pressure that makes a difference in adipocyte trauma. It is well recognized that at pressures higher than 0.5 atm there is adipocyte damage. Thus there are two alternatives: either use a liposuction aspirator where the pressure can be dialed to approximately 300 mm Hg (12 inches Hg), or use a syringe system that maintains the pressure at about 300 mm Hg (KVAC). The former is readily available in most operating rooms but has the drawback of increased air exposure, with the potential for fat desiccation in the long tubing. The latter provides a gentler closed system with less fat loss. We use both techniques and when the fat is scarce and precious, the closed system is preferable, whereas in patients with ample fat, there is probably no difference.

A completely closed technique for fat harvesting and grafting is performed with the Lipografter (Lipocosm, Key Biscayne, FL). This KVAC spring-activated syringe aspirates the fat at a constant 300 mm Hg pressure throughout the excursion of the plunger. When the syringe is full, pushing the plunger down cocks up the spring for the next cycle of suction and sends the lipoaspirate through a nonclogging tissue valve to a bag where the fat is prepared for reinjection using the tissue valve in reverse mode. The system allows rapid harvesting and processing of larger lipoaspirate volumes; the controlled low pressure harvesting with no air exposure is thought to be safer for adipocytes.

Cannula Size

Smaller cannula sizes theoretically create less donor site trauma and allow removal of smaller lobules of fat, which may revascularize more easily, improve flow characteristics, and reduce trauma during reinjection. An important consideration besides cannula size is *cannula hole size* and the *number of holes*. A 12-gauge cannula with 6 to 8 side holes 2 by 1 mm in size can extract a significant amount of fat despite the small caliber. The total surface area of individual openings on a 12-gauge, 12-hole cannula approaches or exceeds the hole size of the classic 10 mm one-hole cannula used in the 1980s, and produces much less donor area trauma. Further, each hole selects for lobules of uniform small size, which are more likely to flow easily through the injection cannula during the grafting phase of the procedure without the need for further processing.

We have found that increasing the number of holes in the cannula while amply compensating for the lower vacuum force improves harvesting efficiency. Our preferred cannula is 12-gauge (2.7 mm), with 9 to 12 side holes of 1 by 2 mm each.

Varying Negative Pressure and the Number of Cannula Holes

We have found that a 6- to 12-hole cannula operating at 0.33 atm is just as efficient in harvesting fat as a single-hole cannula operating at 1 atm of pressure.

Choice of Donor Site

It has been postulated that specific donor areas may promote increased survival of grafted fat. Clinically we have not observed the anatomic location of donor fat to be of significance in our patients. This is consistent with the results seen in limited animal studies. What is more important to consider is the volume requirements for donor grafting in each individual case and the donor areas with relative abundance to meet that requirement.

The surgical plan should try to avoid or minimize creation of any donor site deformities. It may turn out that adipocyte cell size, which varies in different body regions and among patients, may be a more important variable. Larger cells have a higher likelihood of mechanical cell membrane damage during extraction, and this variable of cell size relative to cannula hole size may prove more critical than the specific body area selected for harvesting.

Using fine (2.4 mm) cannulas, we can afford to harvest through a multitude of needle stick entry sites that leave essentially no scar, thus allowing a more diffuse harvest with less chance for contour irregularities, even in the most slender of patients.

Air Exposure

Another variable of unknown import in fat harvesting remains the negative impact of air exposure. Despite its widespread mention, there is a paucity of scientific data quantifying the effect of air exposure on adipocyte viability. Fat processing techniques range from completely high air exposure systems whereby fat is dried on Telfa rolls to completely closed systems employing intravenous tubing tissue valves and bags for collection and reinjection (see p. 2317). In addition to reducing air exposure, closed systems reduce the likelihood of bacterial contamination.

Fat Processing

Peer's cell survival theory of grafted en bloc fat dates back more than 50 years and suggests the number of cells transferred at the time of transplantation may correlate with the ultimate fat graft survival volume. Following Illouz's application of liposuction, fat became available in a fragmented form. The cell survival theory of solid fat transplantation may have served as the initial logic for high-speed centrifugation and hyperconcentration of graft, but this paradigm requires reexamination.

Centrifugation is the chosen method of fat processing that has been popularized as a potential strategy for effective fat grafting. Historically, our penchant for centrifugation arises from the need to graft as much adipocyte biomass as possible into a limited space.

Although centrifugation can process highly concentrated fat, there are six potential problems with centrifugation:

1. Adipocytes may be damaged by the high G forces.
2. It is a time- and labor-consuming process.
3. Adipocytes trapped in the concentrated centrifuged paste have less recipient contact and ability to engraft than loosely dispersed adipocytes.
4. There is increased risk of overgrafting with a concentrated paste.
5. The flow of the pastelike graft is more difficult during reinjection.
6. There is a loss of beneficial growth factors, platelets, and other components present in the gross lipoaspirate.

Concentrating adipocyte stem cells and remixing them with mature adipocytes to increase cell viability is an exciting prospect. The theoretical benefit of a stem cell-enriched graft is that the stem cells promote neovascularization to the recipient site, improving yields. Although this may be an effective strategy in the future, there is no evidence today that it provides a worthwhile advantage over conventional fat grafting. Washing harvested graft with cell preservatives that stabilize the cell membrane and repair “holes” resulting from trauma has recently been described and may have a role in improving percent yields. We do not employ these techniques, since they are not currently FDA approved.

One of the most confusing metrics in fat grafting is a lack of standardization when one discusses *percent yields*. Once fat is lipoaspirated as a donor graft, there is an infinite number of different concentrations of adipocyte volume relative to non-adipocyte volume (blood, serum, crystalloid solution) that can be reached before grafting the recipient site. Unless the concentration of adipocytes in the grafted material can be accurately measured and unless the process of fat concentration is standardized, one cannot reliably measure the percent of grafted adipocyte volume that survived grafting.

The Recipient Site in Fat Grafting

Compared to the attention devoted to graft material and its preparation, the role of the recipient site has been largely neglected in the literature. To better appreciate the role of the recipient site in fat grafting, consider the historical advances of fat grafting compared with those of skin grafting. From descriptions in Sanskrit, small skin grafts were taken by Hindus in 3000 BC after preparing the donor area (usually by beating the patient’s backside) to increase edema and dermal thickness. Several thousand years later, improvements in instrumentation afforded more-uniform donor thicknesses. During the past 60 years in the post–World War II era, a combination of more advanced wound care and debridement, antibiotics, and methods of graft immobilization have helped to improve graft take. The introduction of the vacuum-

assisted closure (VAC) method has further revolutionized skin grafting by a variety of postulated effects, including bacterial clearance, neovascularization, and reduction in edema of the wound bed.

Parallels Between External Expansion and Vacuum-Assisted Closure

Negative pressure on the breast creates internal expansion of the breast parenchyma by drawing in more fluid and increasing the size and caliber of blood vessels.

This patient is shown before and 3 weeks after Brava expansion, immediately before grafting. The volumetric increase is three to four times that of the preexpansion state. A total of 380 cc of fat was injected into each breast.

This MRI of the breasts of this patient demonstrates the contrast in her breasts before and 3 weeks after use of the Brava preexpansion bra 10 hours per day. As can be seen, there is significant expansion of the breasts, with the creation of a larger and more fertile recipient matrix that will allow more fat grafts to be placed. There is an evident increase in the number and size of blood vessels.

We postulate that the external expansion process enhances fat grafting results in five ways:

1. Bigger potential spaces are available for larger graft volumes.
2. Reduces demand on adipocytes to create the expansion, which may destroy them.
3. Augments tension on internal constrictions and scars, so breast *shape* can be addressed.
4. Variables that are time consuming (such as centrifugation) become less demanding.
5. Angiogenesis effect may increase recipient site capillary density and oxygen tension and improve graft take.

The increased parenchymal space created by external expansion before fat grafting permits more volume of graft to be inserted before high subcutaneous interstitial pressures. It is this high interstitial pressure that often limits the graft volume that can be achieved in more conventional grafting techniques. Our collective experience with nearly 100 patients treated with external expansion and fat grafting revealed that the single most important determinant of final volume augmentation was the pregrafting volume expansion. We demonstrated a linear dose-response curve with better expansion, leading to larger augmentations.

The concept of megavolume grafting after expansion is illustrated. The block of tissue is first shown as maximally filled with fat grafts; it is then overfilled to crowding; next, temporary three-dimensional stretching is done of that block of tissue, showing how many more grafts can be placed in the expanded and hypervascular space.

With Brava preexpansion, the patient and the expansion bra drive the volume of expansion, not the injected fat. In conventional fat grafting techniques, grafted fat is required to act in four key ways:

1. To serve as an internal positive pressure expander
2. To survive by oxygen diffusion for 5 to 7 days
3. To eventually reconnect its capillary circulation to that of the recipient site
4. To remain viable and to act as a spacer

This first demand, the internal positive pressure expansion, theoretically works against the other three demands and probably leads to adipocyte necrosis. Brava potentially relieves the adipocyte from this first burden.

Many breasts demonstrate a range of deformities, from subtle, often underappreciated, internal ligamentous constrictions to tuberous or severely constricted breasts. Some of the more subtle effects, like occult double-bubble deformities, are only appreciated at the time of prosthetic breast augmentation when internal tension and volume changes exacerbate these underlying deformities. Using our external preexpansion system before fat grafting serves two valuable functions in reshaping breasts:

1. Deformities, even subtle ones, can be demonstrated to the patient before any surgical intervention is performed.
2. During fat grafting, internal scar ligaments can be selectively lysed percutaneously using three-dimensional mesh grafting, or the Rigottomy technique, described on p. 2334.

By increasing the recipient site space, there is less dependence on concentrating the donor volume, which may reduce the need for time-consuming, high-speed centrifugation and syringe-to-syringe fat transfer. Eliminating high-speed centrifugation from our procedure has resulted in the following advantages:

1. Reduced transfer to smaller syringes, less air exposure, less potential contamination.
2. Less-concentrated fat can be injected, because there is more space in the recipient site.
3. Less-concentrated fat disperses better and leads to less clumping of the graft.
4. Less-concentrated fat flows better, resulting in less clogging and less potential cell trauma.
5. Fat grafting efficiency is improved, allowing the surgeon to graft large volumes even in patients with a low BMI.
6. The operation can be performed in 2 hours or less.

Using the Brava system to preexpand the recipient site has emancipated the technique of megavolume fat grafting from the need for high-speed centrifugation and its potential disadvantages.

Choice of Fat Grafting Technique

Donor cells have the highest chance of survival with the technique that best ensures an even, three-dimensional dispersion of the fat. There are currently two methods of fat grafting: the “mapping” technique and the “reverse liposuction” technique (see technique descriptions later in this chapter). There are presently no data on which technique yields a better result. Each of us employs a different method, yet our independent volumetric data in breast augmentation is nearly identical, with an average volume increase of 250 cc at 6 months by MRI. Overall, the mapping technique may be more suitable for surgeons beginning megavolume fat grafting for breast augmentation, because it is more exacting and deliberate. For breast reconstruction, it is clearly beneficial, especially in scarred areas caused by mastectomy and/or irradiation, where a careful and deliberate graft placement is necessary. The reverse liposuction technique is more time efficient and can be used in cases in which there is no internal breast scarring, no dense adherence of skin to the chest wall, and where the breast is adequately expanded.

Cautions When Grafting Fat to the Breast

In grafting to the breast, the physician should avoid the following:

1. Grafting the parenchyma itself, because it is traumatic to the gland, and there is an increased risk of infection, because the ducts are not sterile.
2. Overgrafting; that is, grafting beyond what the recipient site can bear. A telltale sign of overgrafting is increased tissue turgidity and/or peau d'orange skin changes. Overgrafting often leads to total graft loss.
3. Delivering macropackets of fatty tissue (from which central necrosis will lead to oil cysts) instead of micropackets (which completely revascularize and survive).
4. Uneven grafting and grafting the same area twice to create uneven deposits or lakes.

Once the fat is grafted, the internal breast parenchyma pressure increases and congenital irregularities due to internal ligamentous tethering become more obvious. This is commonly seen at the interface between the natural inframammary fold and the newly augmented breast mound injection area. One of the advantages of fat grafting the breast is its unique ability to correct the constricted, tuberous breast deformity without any incision.

Preoperative Preparation of the Recipient Site

In no other procedure in plastic surgery is the preoperative preparation more vital than in fat grafting to the breast with Brava preexpansion. Mammograms are performed on all patients to obtain a baseline screening for breast pathology. Patients have three-dimensional MRI or three-dimensional photographic imaging to determine preexpansion baseline volume. Before expansion begins, candidates for the procedure are given a specific “goal volume” to achieve and agree they will follow the expansion guidelines. On a volumetric basis, a quantitative doubling of breast volume is the minimum goal set.

The expansion bra is then fitted on the patient by the nurse or by the surgeon, who makes certain that the patient can apply the bra and achieve the suction on her own. The bra comes in several dome projections and in several base diameter sizes and the correct size must be selected for each patient. It is important to educate the patient how to apply the bra so there is no room for error or lack of compliance during the expansion process.

Surgeon's Endpoints for Expansion

Surgery is not guaranteed unless the patient adequately expands. Patients are seen weekly in the office to monitor compliance and to quantify the expansion progress, and to make necessary corrections to the program. A standard doubling of breast volume by three-dimensional imaging is realistic and is usually obtained in 3 weeks in patients who follow the program of expansion. Although this process is planned to take 3 weeks, it is not as much a matter of time as it is a matter of adequate volumetric expansion. Some patients simply expand faster and better than others. In our practice, we have seen patients expand to four to five times the initial volumes in 3 weeks, whereas in other cases, we have seen patients who had little or no expansion after the same period of use. The duration of use in terms of hours per day and the negative pressure during use are the two variables that can be modified to achieve the desired expansion.

Patient's Endpoints for Expansion

1-2-3 Rule

It is important to educate the patient about the extent of the desired expansion. Often patients think they need to expand to their desired breast size and then stop, but this is not optimal. The Brava expansion should be greater than the desired volume, so there is a much larger potential space created compared to the desired volume of fat to be grafted. We have developed the “1-2-3 Rule” for our patients so they can easily understand the endpoints of expansion while they visually monitor their progress at home: If you are a “1” and you want to be a “2,” you must expand to a “3.” A patient who wants to double her final volume must triple in expansion.

Technique

Markings

Patients arrive in the operating room on the day of surgery wearing their expansion bra. Preoperatively, the patient is initially marked for areas to be suctioned, and the breasts are marked circumferentially for areas of proposed needle insertions. Any constricted areas are outlined for planned release using the percutaneous three-dimensional mesh release, as described by Rigotti et al. Markings are placed at 8 to 10 proposed sites circumferentially around the breast. Once markings are completed, the Brava bra is reapplied. Once in the operating room under general anesthesia, the patient is positioned supine with the domes still in place and under manual bulb suction. The anesthesiologist monitors the suction intermittently during the liposuction phase of the procedure, so the negative pressure can still be applied to maximize the recipient site space.

Harvesting

Liposuction is performed using a 12-gauge 9- to 12-hole cannula. Smaller cannula sizes produce less subcutaneous tissue trauma, promote faster recovery, and create smaller fat parcels that result in better fat flow and less clumping. Multiple holes facilitate fat removal increasing both efficiency and speed. Two collection techniques are currently employed.

Syringe Collection Method (Khoury)

Lipoharvesting with the KVAC syringe and a 12-gauge, 12-hole cannula

For the syringe method of fat harvesting, a spring-loaded, 300 mm Hg constant-vacuum (KVAC) syringe is connected with a nonclogging atraumatic tissue valve and intravenous tubing to a 100 cc sterile intravenous bag on the field. Cocking the spring activates the syringe suction, and once the syringe is full, pushing the plunger down again purges the lipoaspirate to the collection bag and cocks the spring again. The cycle is repeated until the bag is full, at which time the assistant replaces it with another empty bag. Fat is harvested in a completely closed system. There is no exposure to air and minimal chances of bacterial contamination. Excessive air exposure is known to be detrimental to adipocyte survival. This technique initially collects the fat into 100 cc intravenous bags, which is efficient for the next step in the process.

Machine Method (Del Vecchio)

Using a sterile “in-line” container, fat is aspirated at lower than 1 atm (500 mm Hg) suction by attaching a sterile, clear, collection canister to a standard vacuum machine off the sterile field. A 3 mm 9-hole cannula with a wide handle and ribbed connector end is used to attach to the liposuction tubing. Maximal negative machine pressures are avoided when using this technique, and vaporization of the fat in the

collection canister is to be avoided at all costs. This technique initially collects the fat into 1200 cc canisters and can be performed with existing equipment used in an operating room.

A 3 mm multihole cannula fused to an ergonomic handle reduces operator fatigue and reduces instrument breakdown at the handle-tubing interface.

The in-line system is shown, with left-hand tubing going to the cannula and right-hand tubing headed off the field to a liposuction machine. The sterile canister on the field collects the fat.

Fat Preparation

Once the fat is collected, one of two general methods for removing unwanted crystalloid solution is employed: the bag centrifugation method advocated by Khouri and the large syringe method advocated by Del Vecchio.

Bag Centrifugation Method

With the bag centrifugation technique, 100 cc intravenous bags are hung on a hand-spun 5:1 gear-ratio spinner and centrifuged at low rpm (approximately 30 G) for several minutes. It takes minutes to prepare the 600 to 800 cc we often need for a bilateral augmentation, compared with hours for high-speed centrifugation. The infranatant crystalloid solution is tapped off, and the fat is ready for reinjection.

Large Syringe Method

By changing several in-line collection canisters during the machine liposuction, the canisters are allowed to stand for 10 minutes, allowing fat to separate from crystalloid. This fat is then drawn up into 60 cc syringes directly from the collection canister, and placed in a megavolume centrifuge. Additional low G force centrifugation of these 60 cc syringes is optional.

In the large syringe method, the passive use of 1 G separates the fat from the unwanted crystalloid solution by the use of stiff collimated containers—the canister and then the 60 cc syringes. This occurs passively and takes minimal additional time.

A number of 60 cc syringes are shown loaded onto the sterilized low G force bucket-handle centrifuge. Spinning decanted fat for 3 minutes at 40 to 50 G results in removal of 15% to 20% additional crystalloid solution, as demonstrated.

The greater the overexpansion of the recipient site space, the less important is production of ultraconcentrated fat. Overexpansion of the recipient site affords the opportunity to inject less-concentrated fat, which theoretically less traumatized, flows better, disperses better because it is less concentrated, and takes less operative time and manpower to process. The emphasis on *overcorrection* of fat grafting, with resultant overcrowding, interstitial hypertension, and fat necrosis, can now be applied to *overexpansion* of the recipient site before fat grafting.

Washing the cells with saline solution is avoided, because it is thought that this may remove essential components such as stem cells and growth factors from the fat slurry.

Placement

Once the fat is separated from unwanted crystalloid solution, injection into the breast begins. Injections are performed using a 15 cm Coleman side-hole needle.

The Mapping Technique (Khoury)

If a closed-system bag collection and centrifugation technique is used, the fat is simply drawn back out of the intravenous bags using small (3 to 5 cc) handheld syringes that are connected directly to a 14-gauge blunt, curved, side-hole cannula.

Markings for the mapping technique for fat injection in the expanded breasts are shown.

The markings are made in the recipient areas to aid in the systematic, diffuse, and even injection of the entire recipient site. Ten to 12 circummammary and 4 circum-areolar needle puncture entry sites are usually made with a 14-gauge hypodermic needle. Radially fanning tunnels from each site provide well-distributed, diffuse sites for insertion of the grafts.

Through each entry point the 15 to 25 cm long cannula makes multiple tunnels that fan out radially, and 2 to 4 cc of fat suspension is injected on withdrawal. The cannula is then inserted into another adjacent entry point and the process is repeated to yield a three-dimensional weave pattern that crisscrosses the recipient space to provide even coverage. The grafts are deposited at multiple levels, deep from the subpectoral plane, to the pectoralis muscle, to the base of the breast just above the pectoralis fascia, to the subcutaneous space immediately subjacent to the dermis.

Care is taken to disperse the graft as much as possible and *to inject on withdrawal of the needle* along an axial track. In a well-expanded breast, the superficial tissues from the skin to the breast parenchyma open up into three potential planes. Fat is first grafted in the most superficial subdermal plane, then in the middle subcutaneous plane, then in the deeper periglandular space. These are staggered along the multiple entrance needle holes. Grafts through the even-numbered holes are distributed most superficially, odd-numbered ones deeper, and periareolar deepest. We prefer to first fill up the preglandular recipient site, because it is more effective than filling the deeper subglandular layer when the same volume of fat is placed and survives. (Golf balls provide more contour projection when placed under the sheet compared with under the mattress).

In a well-expanded breast we can often graft over 200 cc in this superficial plane. Care must be taken, however, to avoid the “peau d’orange” effect of excessive grafting since this will cause total graft loss. Then, if there is more graft available, we graft

the deeper planes beginning under the muscle, progressing to inside the muscle, to above the fascia, to subglandular. Direct injection into dense breast tissue is not performed. This technique is more accurate and deliberate, requiring more time. It is recommended for those who are initially performing fat grafting to the breast. In addition, it requires that the operator deploy the plunger and withdraw the needle at the same time.

Reverse Liposuction Technique (Del Vecchio)

If fat has been harvested and collected using the machine and large syringe technique, the fat is already in 60 cc syringes. These syringes are simply loaded onto the Coleman cannula and injected into the breast. The reverse liposuction technique uses 6 to 8 insertions on the breast along the inframammary fold and spaced 4 to 5 cm laterally toward the axilla. The inframammary fold insertions are usually made 1 cm below the native inframammary fold, because this will descend 1 to 2 cm, similar to the effect seen in augmentation with breast prostheses.

Insertion holes are positioned in a pattern around the breast periphery. Insertions along the medial upper quadrant are generally avoided to reduce the possibility of pigmented large needle scars, as this is the part of the breast often seen in low cut clothing. Using a “reverse liposuction” technique, gentle pressure is placed on the plunger of the 60 cc syringe and the cannula is inserted and removed in a relatively rapid fashion along multiple axial directions.

A straight, 15 cm, blunt, side-hole, 16-gauge Coleman cannula loaded directly onto 60 cc syringes is used to inject the fat using a controlled “to and fro” liposuction movement with constant light depression on the plunger. With every pass of the cannula the direction is changed slightly to create a fanning vector pattern. This is repeated in each different insertion site and at multiple planar levels from the base of the breast. The axillary insertion is also used to place graft tissue in the submuscular position; this approach is thought to be the safest method of navigating the subpectoral space. An example of optimizing a technique versus maximizing a variable, the reverse liposuction technique strives to optimize graft insertion times with the potential for less exact dispersion of fat if not effectively performed. Another potential benefit of the reverse liposuction technique is that 60 cc syringes generate lower maximum pressures than do 5 cc syringes, which generate higher pressure. Therefore, if there is a blockage of flow along the insertion cannula because of clumping, this will occur at a lower pressure using a 60 cc syringe, with less potential damage to the grafted cells and less likelihood of pushing the blockage through, creating a bolus.

The maximum pressure generated in a 60 cc syringe is lower than that of a 3 or 5 cc syringe. There is thought to be less pressure and trauma on the adipocytes using the larger syringe. If the graft is placed at a rate of 1 cc of volume in 2 to 3 seconds, this results in 2 to 3 minutes per 60 cc syringe of fat, or 10 to 15 minutes to augment 300 cc of volume into each breast.

A summary of the two techniques is outlined in the table.

Comparison of Techniques for Harvest, Preparation, and Grafting of Fat

	Syringe Method	Mechanical Methods
Aspiration cannula	12-gauge Luer-Lok	3 mm ergonomic handle
Aspiration force	Handheld syringe	Machine assisted
Operator ease of use	Springloaded	Vacuum unit
Air exposure	Minimal to none	Mild to moderate
Negative pressure	Constant	Constant
Collection chamber	100 cc IV bag	1200 cc rigid canister
Crystalloid separation	Low G force centrifuge	Low G force centrifuge
Injection cannula	16-gauge blunt curved	16-gauge blunt straight
Injection force	3 cc syringe (high)	60 cc syringe (low)
Injection technique	Mapping	Reverse liposuction

Aesthetics of Breast Size and Shape Immediately After Grafting

There is a major paradigm shift between what a surgeon should expect from an aesthetic perspective after prosthetic breast augmentation and augmentation using megavolume fat grafting. Using breast implants, the “on-table” aesthetics can be critically examined for size, symmetry, and position and are more “WYSIWYG” (what you see is what you get). In contrast, the immediate on-table result with megavolume fat grafting represents the first stage of a dynamic process. First, there is a volume of interstitial fluid from the expansion itself and crystalloid solution in the donor fat; this will reabsorb in the first 3 to 5 days after grafting. The surgeon should not be too concerned with the appearance of breasts that look too large on the table but should focus on the volume of material that was grafted. Second, because the augmentation is intraparenchymal rather than the single-cavity volume enhancement achieved with implants, there are more on-table surface irregularities that will resolve in the early postoperative period; these require no additional manipulation.

When external negative pressure is placed on the breast, Brava preexpansion may accentuate breast contour irregularities that are caused by inframammary fold constrictions, tuberous breast constrictions, or internal scars in the breast. It is important to recognize these irregularities while the patient is still on the operating table. Breast shape can be addressed in augmentation patients, especially double-bubble contour deformities that occur along the inframammary fold.

***Shape Modification Using Three-Dimensional Meshing:
The Rigottomy Technique***

We use a technique first described by Gino Rigotti to release scars in breast reconstruction with fat grafting. He performs a three-dimensional mesh release of the scar. This is a very powerful way to release a contracture without making subcisions; it also avoids creating linear tissue planes that end up as loculated cavities with fat necrosis. Instead, the technique releases the contour deformities of the breast parenchyma and expands it in three dimensions like a skin graft is meshed to expand in two dimensions. This creates multiple microcavities where small deposits of fat can survive. We have named this technique the Rigottomy. The grafted fat fills the small cavities in the three-dimensional released structure and restores the attractive, round breast shape. By percutaneously releasing fibrous constrictions, the inframammary fold can be lowered, the constricted tuberous breast can expand in three dimensions, and the overall shape of the breast can be modified dramatically.

Immediately after fat grafting, the injected fat provides an internal traction effect to help identify specific areas of deforming scar or ligamentous bands, as seen in this patient (*left*). After insertion of an 18-gauge needle and release of the scar bands (*center*), the irregularity is released and the fat immediately fills the space created, changing the shape to a more aesthetic result (*right*).

In a dense breast that exhibits a double-bubble contour deformity at the inframammary fold (*right of nipple*) and upper pole (*left of nipple*), multiple needle band releases, or Rigottomies, may be required, as seen in this patient.

Postoperative Management

Postgraft care is a very important factor in graft survival. One would not expect a skin graft to survive if it were subjected to motion and shearing in the early postoperative period. Therefore, in the first 24 hours after grafting, no external compression or negative pressure should be applied. Beginning 24 hours after grafting, patients are placed in Brava domes that are set at a low constant pressure; the patient wears the Brava bra for the first 5 to 7 days after the grafting procedure.

The use of Brava in the postoperative period may act as a splint. As a fundamental principle of plastic surgery, it is crucial to maintain surgically released and grafted constrictions or scars open with a splint until the graft matures. The low negative pressure exerted by the expansion bra may help immobilize the fat cells and aid in neovascularization to the graft. It is also postulated that the lipoaspirate-filled slurry in the interstitial space held open with the Brava bra functions like a multitude of growth chambers to stimulate fat formation. In any event, application of the bra in the postoperative period certainly protects the breast from external trauma, which could serve to shift the grafts and potentially disturb neovascularization.

Our experience has shown that if the patient continues to wear the Brava bra after the first postoperative week for 10 hours per day for several months, she will tend to keep the early augmentation result as permanent tissue, with very little volume loss over the next year. In essence, this is the original expansion effect boosted by fat grafting. Therefore we currently recommend that the patient maintain the external tension on the tissue for 10 hours per day over the next 8 to 10 weeks; this in our experience greatly enhances the megavolume graft results. This creates a multitude of active growth chambers in which Morrison et al have shown stimulation of fat growth.

Results

One-Stage Breast Augmentation

This 24-year-old nulliparous woman desired increased breast size. She was concerned with size and requested a rounder shape. Her breasts were relatively symmetrical, with moderate inferior constriction in the lower poles. She did not want breast implants. She initially underwent expansion with a Brava handheld pump used 8 hours per day for 3 weeks. She was a very compliant patient, and her expansion proceeded well over serial office visits. After 3 weeks of expansion she underwent injection of 280 cc of fat into each breast, harvested by liposuction of the thighs. Six months after grafting, her result is stable. Even in patients in whom liposuction alone would not likely be considered, it is possible to obtain a sufficient amount of fat.

One-Stage Breast Augmentation for Deflated Breasts After Implant Removal

This 59-year-old woman had previously had silicone breast implants that were removed 15 years earlier because of implant complications. At the time of her implant removal, her breast tissue had atrophied and thinned, and her surgeon had performed a Wise pattern breast lift to remove excess skin. The patient was not happy with the size reduction and with the deflated appearance, but she did not wish to undergo reinsertion of breast implants.

When she presented for a thighplasty involving initial thigh liposuction, to be followed 6 to 8 months later by a medial thigh lift, the possibility of using the liposuction fat for her breasts was discussed with her. The patient wore the Brava bra, using the higher-pressure hand pump, for 3 weeks preoperatively during the late afternoon/early evening for approximately 8 hours per day. This patient, a practicing physician, had a busy schedule, and compliance was a challenge. Despite her less than ideal compliance, she had enough parenchymal and skin laxity to expand well and to receive 600 cc of fat in each breast during her thigh liposuction. After 6 months she demonstrated a significant, sustained volume increase. Patients who have breast implants removed have already had significant skin expansion as well as subcutaneous parenchymal redundancy once the implants are removed. This is an opportunity to “backfill” this space with fat.

Two-Stage Breast Augmentation for Constricted Tuberous Breasts

Constricted tuberous breasts can be augmented and reshaped with external expansion and megavolume fat grafting; usually two stages are required to achieve sufficient volume.

This 32-year-old patient with tuberous breast deformity desired increased breast size and improved shape. She had constricted inframammary folds and herniation of the nipple-areolar parenchyma. She did not want breast implants. She initially underwent expansion with a Brava Sport Pump, a low-pressure battery-operated pump, for 3 weeks before her first fat grafting procedure in which 300 cc of fat was injected into each breast, and she underwent three-dimensional mesh release and periareolar reduction. It was thought that the low negative pressure created by the Sport Pump was not optimal and that additional expansion could have been achieved with a handheld pump generating more negative pressure.

Preexpansion MRI of patient

MRI 6 months after second fat grafting

After 4 months she underwent a second round of preexpansion using a handheld pump and had a second round of grafting, with 350 cc of additional fat per breast. Her results after her first procedure and 8 months after her second injection series demonstrate a significant increase in volume and improved breast aesthetics.

Concluding Thoughts

Fat grafting to the breasts fell into disrepute 20 years ago because of a lack of efficacy in technique and the much-discussed potential for obscuring the detection of cancer. Over time, however, these concerns have been largely addressed as applications for fat grafting have expanded.

Today fat grafting to the breast is still controversial, but efficacy is no longer a question. To establish efficacy, each of us has conducted an independent prospective study with a total of 100 patients followed for 6 years. We have carefully monitored our patients with preoperative and postoperative MRIs and confirmed long-term fat graft survival after breast augmentation of 220 to 250 cc per grafting session. None of our patients had a suspicious lesion, and breast radiologists have identified no significant findings on the imaging.

There is no support in the literature for the theory that fat grafting might stimulate the growth of breast cancer. Plastic surgeons have routinely transferred large amounts of fat for breast reconstruction. That experience spans a few decades and hundreds of thousands of patients, with no suggestion whatsoever of increased cancer recurrence in a cancer-prone recipient site. Delay and Rigotti have reviewed their decade-long experience with more 1000 patients grafted after mastectomy and lumpectomy and found no evidence to suggest that the procedure promotes cancer growth or recurrence even in the cancer prone residual breast.

The potential but unproven benefits of stem cell–enriched fat and cell protectants are exciting new avenues for investigation; these must be evaluated through clinical studies, comparing these results to those using unadulterated adipocyte grafts as a benchmark. Over the next decade, these issues and the relative safety of the procedure will be better defined. Standardization, clinical improvements in technique, and protocols for preoperative and surveillance breast imaging are needed to define patient safety and the role of fat grafting as a viable alternative for breast augmentation.

Clinical Caveats

Successful fat grafting requires optimization of four components: (1) the grafted tissue with its viability and growth potential, (2) the size and quality of the recipient site, (3) the grafting technique, and (4) care after grafting. The outcome will be as good as the weakest link. There is no point in investing excessively in one factor if another step is neglected.

Preparation of the recipient breast with the Brava external expansion system requires a minimum of 2 weeks of expansion.

The more intensive the use of Brava, the faster the expansion; patient compliance is essential.

Expansion makes the recipient tissue compliant and allows the diffuse placement of large graft volumes with optimal preservation of the graft to the recipient interface.

For patients with constricted tuberous breasts, the Rigottomy technique is beneficial. It provides for the percutaneous release of fibrous constrictions in the inframammary fold so the constricted breast can be expanded in three dimensions, thereby facilitating the modification of the overall shape of the breasts.

CHAPTER 65

Fat Grafting to Treat Capsular Contracture

GINO RIGOTTI, ALESSANDRA MARCHI,
GUIDO BARONI, PAOLO PATETE, ANDREA SBARBATI

Capsular contracture is a postoperative complication following aesthetic and reconstructive surgery of the breast. Clinical studies report an incidence of 7% to 20%, without any specific correlation with the surgical procedure (augmentation or reconstruction).

From a clinical standpoint, capsular contracture results from a progressive fibrotic physiologic process that follows the insertion of a foreign body; the body attempts to wall off the object. After breast augmentation surgery in which implants are placed, normal capsule formation leads to a thin, soft layer of fibrotic tissue around the implant, with no evident morphologic modification of the breast. Capsular contracture is characterized by progressive hardening and thickening of the periprosthetic tissue layer, leading to retraction. The result is deformation of the implant, resulting in evident breast morphologic changes toward a hemispheric shape; the breast is drawn upward, causing pain and, in the worst cases, extrusion of the implant. Although the causes of capsular contracture have not been entirely elucidated, postoperative radiation therapy has been reported to significantly increase its incidence.

According to Baker's classification, capsular contracture is grouped into four categories:

Baker I capsular contracture is characterized by a soft breast without significant scar tissue.

Baker II capsular contracture involves palpable scar tissue around the implant; however, the capsule is not visible.

Baker III capsular contracture is associated with visible and palpable hardening, leading to a deformed breast shape.

Baker IV capsular contracture, the most severe level, involves hardening and a palpable, visible capsular deformation and often a cold, hard breast that is very painful even to mild palpation.

Capsular contracture is conventionally treated with surgery (typically implant replacement) or capsulectomy in an attempt to restore normal breast morphology and reduce the clinical symptoms. However, in a high percentage of cases, the beneficial effects of surgical revision are not long lasting, and the contracture redevelops, requiring further surgical intervention.

The use of autologous fat grafting for the treatment of capsular contracture was first attempted after observation of the substantially fibrotic and avascular nature of the periprosthetic tissue.

This microscopic image of a periprosthetic capsule indicates the presence of contracture. This is typical of ischemic tissue, with no or few blood vessels present. Recent clinical studies demonstrate that transfer of lipoaspirate (autologous fat grafting) is an effective treatment for many of the pathologic conditions related to ischemia. Thus fat grafting is proving a reliable therapeutic strategy for the treatment of capsular contracture.

Although the mechanisms associated with the regenerative properties of lipoaspirate are not yet completely understood, they have been explained by the action of mesenchymal multipotent cells, *adipose-derived stem cells* (ADSCs or ASCs), which have been found in significant quantity in harvested lipoaspirate. The capability of these cells to produce angiogenic and growth factors appears to be enhanced when they are grafted in a biologic environment with altered microcirculation or when fat grafting is followed by mechanical stretching for volumetric enhancement.

The advantages of fat grafting in clinical practice include the ease and accessibility of harvesting lipoaspirate from different donor areas, the simplicity of the purification procedure, and the permanent nature of the results of fat transfer. The use of micrografts has led to improved “take” of the transferred lipoaspirate.

The advantages of fat grafting in the treatment of severe postradiation effects are demonstrated in this patient. On the left, she is seen following radiation therapy. On the right, after autologous fat grafting, a newly generated thick layer of fatty tissue is evident during reconstructive surgery.

Indications and Contraindications

Women who have had implant-based reconstruction or cosmetic breast augmentation and developed severe capsular contracture (Baker grades III or IV) are ideal patients for fat grafting. Many of these patients have undergone a conventional approach to the treatment of capsular contracture, and the condition has recurred.

Patient suitability for fat grafting depends on whether the individual has a sufficient amount of fatty tissue to be harvested (70 to 200 cc for each grafting session; on average, three or four sessions are required). There are no specific contraindications to fat grafting, such as patient age or health issues, as long as the patient is able to tolerate the deep sedation required for tissue harvesting and grafting.

Preoperative Assessment and Planning

The severity of capsular contracture and its location must be carefully assessed so the surgeon can estimate the correct amount of fatty tissue required and make a preliminary comparison of the volume available at the donor site in relation to the requirements of the recipient site, without putting too much pressure on the infiltrated lipoaspirate. Generally, no additional fat is grafted to account for absorption; the effects of absorption are reduced by repeated lipoaspirate sessions. Grafting features fat deposition in a large area around the contracture site, plus localized deposition to treat the most evident signs of retraction and fibrosis.

Fat grafting is planned by establishing the number and location of the entry points and the direction of the injection tunnels; these parameters can be refined during surgery. The goal is to achieve optimal uniformity of distribution around and within the contracture area and to avoid significant overlaps and gaps. Lipoaspirate must be distributed all around the capsule with no perforation of the capsule or the prosthesis. The purified fat is grafted between the skin and the capsule.

Surgical planning can be enhanced with computer-assisted planning tools. These provide volumetric anatomic models of the target area based on MR scans (with the patient prone), or they register an MR atlas on the patient's surface data acquired by laser surface scanning. An example of the targeted volume and graphic feedback of optimized tissue deposition pathways is shown above. The computer tool allows the surgeon to visualize and segment the target structures, to establish the initial graft geometry by defining preliminary entry point positions and insertion angles, and to define forbidden areas and/or volumes that must be avoided, such as the implant. The tool features automatic procedures that optimize the grafting sequences by means of volumetric algorithms that optimize the uniformity of tissue distribution.

The operative plan created with these computer tools can be viewed during the procedure to guide the surgeon through the sequence of deposition paths. A further step toward the highest possible accuracy of fat grafting is represented by the use of intraoperative surgical navigation devices based on real-time, three-dimensional localization technologies (infrared optical tracking systems and electromagnetic localizers) that are registered with the individual patient's surgical plan.

The surgeon must thoroughly discuss the procedure with the patient, particularly the fact that the technique requires multiple surgical sessions at monthly intervals and that the entire treatment cycle can be as long as 12 months.

Operative Technique

The operative technique is organized in three phases.

Phase I: Harvesting the Lipoaspirate

The patient is given a local anesthetic and deep sedation for harvest of fatty tissue. Twenty minutes before surgery begins, antibiotics are administered. Typically, lipoaspirate is harvested from the medial area of the knee, the abdomen, or the trochanteric regions and the flanks. The identified donor area is infiltrated with a cold saline solution of 1:400,000 epinephrine and 20 ml lidocaine 0.5% for every 500 ml. Harvesting is performed by means of a 2 mm diameter blunt-tip cannula with a dull distal opening that is connected to a 50 cc Luer-Lok syringe. Aspiration must be performed without applying excessive negative pressure. It is important to begin harvesting with superficial liposuction, extending this to the deeper layers.

Phase II: Purifying the Lipoaspirate

The harvested fatty tissue is purified to remove a large part of the triglycerides stored in the tissue to facilitate their rapid clearance after injection. At the end of harvesting, the cannula is removed from the syringe and replaced with a plug. The plunger is removed and the syringe is placed directly into a centrifuge (IEC Medispin-6). The syringes are centrifuged at 1000 rpm for 1 minute; this produces three layers within the syringe: the upper level contains oil from ruptured adipocytes; the middle level contains the purified lipoaspirate; and the lowest level contains blood, saline solution, debris, and residual drugs. The upper and lower levels are discarded by using neuropads for absorption and opening the plug, respectively. The purified lipoaspirate is transferred to a 2 cc syringe and is ready for injection.

Phase III: Injecting the Lipoaspirate

The same local anesthetic that is employed for harvesting is injected at the recipient site with the patient under deep sedation; blunt needles are used to avoid vessel damage. Coleman type III and V cannulas are used for lipoaspirate deposition (especially effective in irradiated tissue).

There are two main issues to be considered in lipoaspirate deposition:

1. The quantity of lipoaspirate to be administered
2. The homogeneity of the deposition

The quantity of lipoaspirate to be injected is crucial. Several issues need to be considered: stiffness of the subcutaneous tissue and skin retraction (*peau d'orange*) are highly critical. The quantity of lipoaspirate is decided on a patient-specific basis. It

is important to avoid too much pressure on the infiltrated lipoaspirate; at the end of the procedure, some elasticity within the treated area must be preserved. It is crucial that fatty tissue be placed with the highest homogeneity within and around the targeted area. Anecdotally, this homogeneity is believed to increase the regenerative effects of the treatment. Graft homogeneity is the rationale for using computer-assisted planning and surgical navigation for lipoaspirate grafting.

As a general rule, the placement of very small aliquots of lipoaspirate for each insertion path is the key to obtaining remarkable, lasting results. Injection of bulky quantities will usually result in the development of oil cysts and/or macrocalcifications. *NOTE: The thread of lipoaspirate must be placed while withdrawing the cannula to minimize the risk of arterial or venous embolization.*

The number of treatments depends on the patient's initial clinical picture and on the patient's response to the therapy. In our experience, three to six treatments are sufficient to obtain the desired results. Capsular contracture following radiation therapy is much more severe and requires more fat grafting procedures. There is no evidence of any contraindication to additional fat grafting sessions.

Postoperative Care

DONOR AREAS Immediately after the procedure, ice packs should be placed for 4 to 6 hours over any areas from which fat was harvested. The patient wears an elastic pressure garment for about 2 weeks.

TREATED AREA As in the donor area, ice packs are positioned over the treated area immediately after the procedure and kept in place for 4 to 6 hours.

Immediate and Late Complications

Donor Areas

In the postoperative period, ecchymosis and small hematomas are often present but normally disappear within 2 to 3 weeks. Local administration of epinephrine is extremely important to avoid this problem. Irregularities can be avoided by using the techniques recommended for liposuction.

Infection

Infection is a very uncommon complication—the incidence is normally much less than 0.5%. This probably is associated with antiinflammatory properties of the lipo-

aspirate as a result of T lymphocyte inhibition. Nevertheless, we strongly advise giving a single prophylactic dose of an intravenous antibiotic before the procedure.

Venous and Arterial Injuries

The most common problem associated with fat grafting is damage to veins or small arteries, resulting in ecchymosis, and occasionally hematomas. To avoid these problems, sharp needles should not be used, even for injection of a local anesthetic. Peripheral arterial occlusion has never occurred in any of our patients after the procedure.

Results

In this patient, total reconstruction of the right breast with an implant was complicated by moderate capsular contracture. There were wrinkles that were more evident in the upper quadrants and flattening of the lower pole, as well as upper prosthesis dislocation and a volumetric deficit. Four fat grafting sessions were sufficient to resolve the scar retraction and contour waviness and to produce new adipose tissue in the targeted areas; this led to restoration of breast morphology comparable with that of contralateral breast.

This patient underwent implant-based breast reconstruction, which resulted in a significant Baker III capsular contracture. Retraction had led to upward dislocation of the implant, with excessive bulging in the superior quadrants and deformation of the inferolateral contour. Marked scar retraction was also evident. At her 5-year follow-up, we modified the capsular fibrotic tissue through fat grafting into a softer tissue, which led to complete morphologic and clinical recovery.

In this patient, breast reconstruction with a prosthesis after a quadrantectomy resulted in severe capsular contracture after radiation therapy, with a significant reduction in breast volume, severe retraction of the residual gland in the upper quadrants, and scar adherence to the chest wall. The patient also had pain and restraint of movement.

Three sessions of fat grafting, every 4 months, led to a marked reduction of the general retraction, and restoration of the volume deficit and natural ptosis. The reconstructed breast became soft and pain free. The implant was not replaced.

Before fat grafting

After session 1

After session 2

This young woman underwent total breast reconstruction with a breast implant. No radiation therapy was performed. Localized capsular contracture in the superomedial and inferolateral quadrants affected the cosmetic result. Two fat grafting sessions (80 cc and 120 cc, respectively) were performed to correct gaps and restore contours. The antifibrotic effects of fat grafting allowed resolution of the initial marked capsular contracture, scar retraction, and volumetric deficit.

Before fat grafting

After session 1

This patient had undergone bilateral augmentation and developed significant capsular contracture in the right breast, with a round constriction of the breast and retraction most evident in the inferior pole. Selected capsulotomies and capsulectomies had not improved the clinical picture. Three fat grafting sessions with 4 months between each session were necessary to restore shape, volume, and symmetry with the contralateral breast.

After session 2

After session 3

Fat grafting progressively improves the softness of the breast; the contracture, particularly evident in the upper quadrants, became a wider, rounder shape, and ptosis was increased, allowing the breast to shift downward with a much more natural look.

In cosmetic surgery, capsular contracture is a distressing complication after breast augmentation. This patient developed severe capsular contracture after a bilateral submuscular augmentation in which monolumen cohesive silicone gel textured implants were placed. The patient underwent surgery twice for capsulectomy and replacement of the implants, with no favorable result and a subsequent recurrence. The MR scans indicate the clinical picture before fat grafting.

The patient underwent three fat grafting sessions to reduce contractures and restore normal, stable breast contours. Her long-term results are shown 7 years after the third fat grafting session.

The therapeutic efficacy of fat grafting is based on the regenerative potential of mesenchymal adipose-derived stem cells and has proved to be extremely effective and reliable in the treatment of many different problems, exhibiting a common etiopathogenesis of chronic ischemia. Nevertheless, in some clinical cases characterized by initial major damage, particularly the severe adverse effects of radiation therapy, fat grafting does not correct the problem and implant removal is necessary, as can be seen in this patient who had implant extrusion after a nipple-sparing mastectomy and intraoperative radiation therapy (IORT). Surgical removal of the implant was accompanied by a first fat grafting session.

After removal of implant and session 1

After session 2

Even in unfavorable cases, fat grafting offers alternative solutions, such as total autologous implant-free breast reconstruction. The patient is shown 45 days after implant removal and her first and second fat grafting sessions.

After session 3

After session 4

The same patient's results are seen after her third and final fourth sessions of fat grafting.

Clinical Caveats

The adipose-derived stem cells (ASCs) contained in lipoaspirates modify the fibrotic and ischemic tissue of capsular contracture into soft tissue with restored micro-circulation.

Tissue regeneration induced by fat grafting leads to a restoration of normal breast morphology.

Uniformity of tissue deposition can be optimized by using preoperative computer-assisted planning tools and intraoperative navigation systems.

Harvesting and purification of fatty tissue (centrifugation) are straightforward processes.

Fat tissue deposition is performed between the skin and the capsule in multiple sessions with a 3- to 4-month interval.

Three to six sessions are generally required to obtain stable, long-lasting results.

Annotated Bibliography

Embrey M, Adams EE, Cunningham B, et al. A review of the literature on the etiology of capsular contracture and a pilot study to determine the outcome of capsular contracture interventions. *Aesthetic Plast Surg* 23:197-206, 1999.

This review covers the literature on several proposed contracture factors, including filler material, implant placement, surface texture, and bacterial infection. The pilot study's goal was to test the feasibility of a data collection form that could be used in a scaled-up study to analyze multiple surgeons' records. The goal of the expanded version of this study will be to determine the efficacy of available interventions for capsular contracture, including surveillance.

Kronowitz SJ, Robb GL. Radiation therapy and breast reconstruction: a critical review of the literature. *Plast Reconstr Surg* 124:395-408, 2009.

The optimal timing and technique of breast reconstruction in patients who may require postmastectomy radiation therapy are controversial. Even with the latest prosthetic materials and modern radiation delivery techniques, the complication rate for implant-based breast reconstruction in patients undergoing postmastectomy radiation therapy is more than 40%, and the extrusion rate is 15%. They conclude that in patients who will receive or have already received postmastectomy radiation therapy, the optimal approach is delayed autologous tissue reconstruction after postmastectomy radiation therapy. If postmastectomy radiation therapy appears likely but may not be required, delayed-immediate reconstruction may be considered.

Patete M, Riboldi M, Spadea MF, et al. Motion compensation in hand-held laser scanning for surface modeling in plastic and reconstructive surgery. *Ann Biomed Eng* 37:1877-1885, 2009.

The authors report on the development of a new integrated method for breast morphology assessment in plastic and reconstructive surgery comprising hand-held laser scanning with active compensation of breathing motion and involuntary movements to obtain a thorough, artifact-free representation of patient breast shape. This was obtained by tracking surface motion with a configuration of passive markers fitted on the patient's thoracoabdominal region. The proposed method, based on a mapping procedure, has been compared with respiratory gating, which is commonly used in radiation therapy and biomedical imaging applications. The results show that the implemented procedure is able to compensate for motion, resulting in quantitative surface description to be used for clinical evaluation.

Rigotti G, Marchi A, Galiè M, et al. Clinical treatment of radiotherapy tissue damage by lipoaspirate transplant: a healing process mediated by adipose-derived adult stem cells. *Plast Reconstr Surg* 119:1409-1422, 2007.

The objective of this study was to assess the presence of adipose-derived adult stem cells left in their natural scaffold in the purified lipoaspirate and to assess the clinical effectiveness of lipoaspirate transplantation in the treatment of radiation side effects. This study was designed beginning with surgical procedures in 2002 and envisaging a continuous patient follow-up to 31 months. Twenty consecutive patients undergoing therapy for side effects of radiation treatment with severe symptoms or irreversible function damage (LENT-SOMA scale grade 3 and 4) were enrolled. Purified autologous lipoaspirates (60 to 120 cc) taken from a healthy donor site were administered by repeated minimally invasive computer-assisted injections. This study demonstrates that this surgical procedure is an effective therapeutic approach for resolving the late side effects of radiation therapy. According to the proposed hypothesis of the ischemic nature of radiolesions, treatment with lipoaspirate transplantation is potentially extended to other forms of microangiopathies.

CHAPTER 66

Augmentation Mastopexy

DENNIS C. HAMMOND

Augmentation mastopexy is generally regarded as one of the most challenging of all the aesthetic procedures performed on the breast. This reputation is well deserved because of the thoughtfulness required in designing an appropriate operative strategy and the technical expertise required to perform the procedure. For many patients presenting with ptosis and volume loss, operative correction is more of a reconstructive endeavor than a purely aesthetic one. Thus revisions are often required to obtain an optimal result. This does not indicate that the overall procedure is a failure, but rather is a consequence of handling multiple surgical variables at once. It is with this philosophy in mind that I will outline the principles that govern the design of a successful operative strategy and describe the factors that influence specific implant choice as well as the technique of skin envelope management.

Indications

An aesthetic breast represents a harmonious positional relationship between the footprint of the breast and the location of the nipple-areola complex. When the nipple-areola complex is located in any inferiorly displaced position other than at or slightly above the point of maximal projection of the breast mound, it is considered ptotic. This is not the appearance of an aesthetic youthful breast, the artistic ideal that we strive for. In this context it must be recognized that ptosis of the nipple-areola complex is not an all-or-none phenomenon; varying degrees of nipple-areola complex ptosis can occur. Other variables can affect how the nipple-areola complex position is perceived, including the location of the breast footprint on the chest wall and the presence of pseudoptosis or ptosis of the breast parenchyma and skin envelope in association with a normally positioned nipple-areola complex.

With this in mind, one strategy that can be used to guide a ptosis correction procedure is the location of the nipple in relation to the location of the inframammary fold. When viewed from directly in front, a line can be drawn across the chest connecting the inframammary fold from side to side. If the nipple is located 2 cm or more above this line, simple breast augmentation will provide enough lift to properly position the nipple-areola complex at the apex of the breast mound.

This is an example of a patient who presented for breast augmentation with a normal nipple position. For this woman, a simple breast augmentation can be performed, and the implant and the nipple will be positionally in phase, creating a pleasing result.

In these cases, if the nipple-areola complex position is still a bit low, the inframammary fold can be lowered slightly to reposition the implant below the nipple-areola complex to create the proper nipple-areola complex-to-breast mound relationship and optimize the aesthetic result. Between 0 and 2 cm above the fold, a periareolar mastopexy may be required to create the best result.

This is an example of a patient whose nipples are located just above the level of the inframammary fold. For this woman, the optimal result will be obtained by using a periareolar lift in conjunction with placement of an implant.

Again, lowering the fold may be helpful in bringing all the elements of breast shape and proportion into harmony to create the best result. For patients with nipples that fall below the inframammary fold line, in addition to a periareolar technique, a vertical extension will likely be needed to completely correct the ptosis.

This is an example of a patient whose nipples are located well below the inframammary fold. The skin envelope is loose and redundant. For this woman, a circumvertical mastopexy pattern can effectively lift the nipple-areola complex the required amount and help to manage the redundant skin envelope.

Contraindications

Aside from the purely technical aspects of treating breast ptosis are the concerns patients have regarding the scars that are produced. In particular, for patients who are on the borderline of requiring a periareolar procedure to optimize the aesthetic result, concerns about the periareolar scar may prompt the surgeon to try a different approach. In these patients lowering the fold slightly may allow a reasonable result without the need for a periareolar procedure. It may also be helpful to use an anatomically shaped cohesive gel implant that concentrates more of the volume in the inferior pole of the breast.

This 40-year-old woman requested breast augmentation. She was unwilling to accept the scars associated with a periareolar mastopexy; therefore an anatomically shaped cohesive gel implant was used to concentrate more of the implant volume in the lower pole of the breast and limit the likelihood of any excess upper pole fullness. She is shown 4 years after the placement of a 375 cc anatomically shaped cohesive textured silicone gel implant; the skin envelope has been filled without any excess upper pole distortion. The shape of the breast is acceptable; however, the position of the nipple falls just below the point of maximal projection of the breast mound. For this patient, this was an acceptable compromise, given the fact that there was no periareolar scar.

If patients are advised preoperatively that the nipple-areola complex may still appear a bit low after surgery, this may be an acceptable option if the goal is to avoid the periareolar scar. One maneuver that carries a significant potential for postoperative dissatisfaction is an attempt to lift the nipple-areola complex by using an overly large implant.

This 24-year-old woman is shown 1 year after an 800 cc smooth round silicone gel implant was placed in an attempt to avoid the need for a mastopexy. Although the larger volume device was placed in an attempt to “lift” the breast, all that has been accomplished is the creation of an overly large and out-of-proportion breast that still has a nipple-areola complex that is too low.

This strategy is often unsuccessful in lifting the nipple-areola complex the needed amount and leaves the patient with a breast that is too large, with sharp, unnatural contours. The negative effects of such large devices on the patient’s soft tissues over time make this an unattractive option in nearly every circumstance. For these reasons, the strategy of using a large device in an attempt to lift the nipple-areola complex and avoid the need for a formal mastopexy should be avoided.

Operative Strategy: To Stage or Not to Stage

It has been suggested that one technique that can be used to improve the outcome of an augmentation mastopexy is to stage the procedure by breaking it up into its two component parts. Generally speaking, this involves performing the mastopexy first, followed later by the addition of an implant. The advantage of this approach is that the control the surgeon has over the final result is enhanced by dealing with only one set of variables at a time. By successfully reducing the surface area of the redundant skin envelope, normalizing the position and size of the nipple-areola complex, and letting the final result stabilize over time, more reliable decisions can be made about

the size, shape, and position of the subsequent implant. The disadvantage of this approach is that two procedures are required to achieve the end result, and if any complications develop, a third or even a fourth procedure could be required to achieve an acceptable endpoint. In addition, the financial strain placed on patients using this approach can be significant, leading many patients to abandon the idea altogether. To achieve a reasonable result after the first-stage mastopexy, a significant skin tightening will likely be required that can restrict the size of the implant that is chosen during the augmentation. To perform the procedure in the reverse—that is, to place the implant first and then perform the mastopexy later—is an even less attractive option, since it is very likely that a properly placed implant will ride high compared with the ptotic breast during healing after the augmentation procedure. Thus a temporary but potentially distressing deformity can be created that must be tolerated until the mastopexy is completed.

To avoid these disadvantages, many surgeons perform the augmentation mastopexy as one procedure at the first operation. By intelligently adding an appropriate-sized implant and then tightening the skin envelope around this newly created breast, excellent results can be obtained. If a revisionary procedure is required in the future, it is usually of less magnitude and complexity than would generally be required when using a staged approach. For this reason many surgeons prefer to combine the augmentation with the mastopexy in one operation, accepting the possibility that a revisionary procedure may be necessary in the future.

It has been suggested that one of the reasons that augmentation mastopexy is so difficult is that the technical details of the operative strategy work against one another. In other words, adding an implant enlarges the breast volume and performing the mastopexy reduces the skin envelope, two factors that when taken to excess can compete with each other. It is perhaps more accurate to think of the procedure as enlarging the breast volume the correct amount to allow the still-redundant skin envelope to be reduced to match the new breast volume, thus creating a situation in which the implant and the breast work together to just the proper degree to create an aesthetic breast shape. To achieve such a result requires technical skill and artistry, which for the surgeon is one of the most compelling aspects of the procedure.

Implant Selection

When selecting an implant for an augmentation mastopexy patient, there are slightly different variables involved than those for a simple breast augmentation. First, for many patients with breast ptosis, the skin envelope has been compromised to the point that it has little normal “rebound” under stretch, even after it has been tightened by removing the redundant skin. As a result, the implant is not held in position as tightly as in a breast augmentation patient, where the surrounding soft tissues can

often snugly secure the implant in place. For this reason, *round* smooth or textured implants hold an advantage over anatomically shaped gel devices, because the inherent symmetry of the round device can tolerate a certain amount of implant mobility without risking breast distortion from implant rotation. If an anatomically shaped implant is used, any element of implant rotation in this inherently asymmetrical device can adversely affect the shape of the breast. Such rotation becomes a greater possibility with a looser overlying skin envelope, even when the pocket has seemingly been accurately dissected to match the dimensions of the implant. In addition, augmentation mastopexy patients typically have a greater starting breast volume than primary augmentation patients do, and this inherent volume must be considered when planning the operation and selecting an implant volume. It is common for the average implant volume used in augmentation mastopexy to be slightly less than that used in breast augmentation to achieve an equal result. In fact, it is not at all uncommon for an augmentation mastopexy patient to feel that her breasts are too big after the procedure, because many surgeons apply the augmentation mindset to the preoperative planning process and ignore the preexisting volume of the breast. Therefore, when selecting implant volumes in breast augmentation mastopexy, it is prudent to be conservative to optimize patient satisfaction with the overall result.

Whether or not textured implants provide any advantage in augmentation mastopexy remains unclear (see Chapter 61). Basically, all of the arguments guiding implant selection in primary breast augmentation also apply to augmentation mastopexy. Although the effect of textured surfaces on capsular contracture remains somewhat controversial, many surgeons think that a textured surface will assist in holding the implant in position and perhaps limit the development of recurrent ptosis postoperatively. Such an effect is conjectural at this point, and the use of textured versus smooth devices remains a matter of personal preference.

Pocket Plane Selection

One very important aspect of the preoperative planning process relates to the pocket plane used to place the implant. For augmentation mastopexy patients, this decision can be profoundly influenced by simple anatomic relationships. Quite simply, one of the elements of the overall ptotic appearance of the breast is often a somewhat low breast footprint or a breast position that is low on the chest wall. Even with tightening of the skin envelope, the overall position of the breast in relation to the pectoralis major muscle remains low, and to properly position the implant under the breast, a significant release of the pectoralis major muscle is often required. Failure to do so can create a disharmonious positional relationship between the breast and the implant. As a result, most of a properly positioned implant will in fact extend well below the lower border of the muscle, often with only the upper 25% or less of the implant being covered by muscle.

When a breast implant is placed under the pectoralis major muscle with little or no release in an attempt to provide maximal muscle coverage to reduce the potential of capsular contracture, the implant can be located too high in relation to the position of both the breast and the nipple-areola complex. The result is an unaesthetic breast contour with a rounded upper pole and a nipple-areola complex position that is too low. When the pectoralis muscle is released along the inferomedial border, the implant can then be positioned lower on the chest wall under the ptotic breast mound to create a more pleasing contour with a properly positioned nipple-areola complex. However, in these cases, the muscle may then only cover a small portion of the implant, leaving the device in a space that is mostly subglandular.

Thus it is reasonable to question the utility of placing the implant in the submuscular pocket at all in an attempt to reduce the rate of capsular contracture, since most of the implant is in fact in contact with the gland. Therefore, in patients with adequate thickness of soft tissue in the upper pole of the breast, generally regarded as 2 cm or more, the subglandular pocket can be used to good effect. In fact, subglandular implant placement can have a slightly more prominent nipple-areola complex

elevating effect than even partial subpectoral placement, because all of the projection of the implant is applied in an unrestricted fashion to the overlying soft tissue, with a mild lifting effect on the nipple position. Many surgeons favor the subglandular pocket as a means of providing maximal lift in augmentation mastopexy, because placing the implant under the muscle can limit the projection of the device somewhat, resulting in less elevation of the nipple-areola complex. However, in patients with a thinner soft tissue thickness in the upper pole of the breast (less than 2 cm), the lifting effect of subglandular placement must be weighed against the creation of a sharp step-off in the upper pole. In these patients, the breast-implant interface in the upper pole can be softened by placing the implant in the subpectoral pocket to create a more natural contour, even though the muscle covers only a small portion of the implant. For such patients, shaping the upper pole takes precedence over concerns regarding the lift effect of the implant, and the partial subpectoral space is the preferred pocket for implant placement in thinner patients.

Operative Technique

Periareolar Approach

When contemplating periareolar techniques to assist in the management of the patient with breast ptosis, one must realize that periareolar approaches are excellent techniques for lifting the position of the nipple-areola complex, but they are much less successful for reducing a redundant skin envelope. When a periareolar approach is used to try to reduce the skin envelope while lifting the position of the nipple-areola complex, because of the size of the resulting periareolar defect it is likely that complications will develop, such as wound healing, distortion of areolar shape or size, flattening of breast projection, and/or unaesthetic scar formation. For this reason, performing a periareolar nipple-areola complex lifting procedure in conjunction with an augmentation is limited to patients who generally need 3 cm or less of nipple-areola complex lifting. Such patients can be treated quite consistently and successfully using a periareolar approach. In fact, this subset of patients probably falls out of the augmentation mastopexy category, typically recognized as being technically challenging and prone to complications, because adding a small periareolar lift to a breast augmentation using a periareolar incision is not a technically challenging procedure and is easily done. With that in mind, there are several technical maneuvers that can be applied to periareolar surgery that can help ensure success.

Periareolar Purse-String Suture

One of the recognized complications related to periareolar surgery is postoperative areolar spreading. This tendency of the areola to spread can be minimized in two ways. First, it must be recognized that the areolar dermis is quite elastic, and a given areolar diameter diagrammed into a relaxed native areola will stretch many millimeters once it is placed under tension by an unsupported periareolar closure. For

this reason, any time an areolar diameter is diagrammed as part of an areolar reduction or lifting procedure, the intended diameter must be measured with the areola under maximal stretch to limit the effect of immediate stretch on the resulting postoperative areolar diameter. In a related fashion, any time a periareolar manipulation is attempted, it is advisable to make the periareolar defect completely periareolar to minimize asymmetrical forces from distorting the shape of the areola. One example of this is the use of a crescent-shaped superior areolar resection in an attempt to lift the areola without creating a completely periareolar scar. The unfortunate result of such a procedure can be lifting of the areola at the expense of creating a distorted and vertically oblong areolar shape.

Second, once the periareolar defect has been created, it must be supported with a permanent purse-string suture. By supporting the outer periareolar defect with a purse-string suture, the stress of the closure is absorbed by the purse-string, thus relieving the tension on the areola as it rests within the defect defined by the purse-string as it is closed down. Although many types of sutures can be used for this purpose, two design attributes of the suture become important in providing long-term success. First, a permanent suture material is much more reliable; the long-term support provided by a permanent suture allows the new soft tissue relationships created in the postoperative breast to stabilize over time, reducing the tension on the areola. Therefore, even if the suture fails after a year or more, the likelihood of areolar spreading is minimized because of scar support of the closure, in addition to whatever soft tissue accommodation has taken place over time. If an absorbable suture is used for this purpose, disintegration of the suture with loss of support can occur before the defect has stabilized, possibly leading to areolar spreading. Second, a monofilament suture offers technical advantage when the suture is cinched down, since it slides through the outer dermal diameter more easily without catching or bunching. Perhaps the best material currently available that satisfies both of these concerns is suture made of a polytetrafluoroethylene (PTFE) material, otherwise known as Teflon.

PTFE or Teflon suture is commonly used in cardiovascular and dental surgery because of its handling characteristics and nonreactivity. It is a permanent, strong, monofilament suture with little “memory” and smooth handling characteristics, all

of which makes it the ideal material to use as a purse-string suture. It slides through the tissue matrix of an outer periareolar incision smoothly, allowing precise control of the size of the periareolar defect. By cutting the curved needles of a standard cardiovascular suture strand and threading the suture onto a Keith needle, passage of the suture can be facilitated, allowing the strand to be placed in the fewest number of passes possible. Currently PTFE suture is available from several manufacturers in several different sizes. There is an advantage to using a suture strand that is roughly the size of a standard 3-0 suture attached to a straight (Keith) needle.

Interlocking Purse-String Suture

In an attempt to further stabilize the periareolar defect and minimize postoperative areolar spreading, an interlocking purse-string suture can be used.

This patient presented for revision after a previous periareolar augmentation mastopexy. The interlocking suture technique is planned to control the size and shape of the areola. A 40 mm areolar diameter is diagrammed with the areola under maximal tension and the inner and outer incisions are made. The intervening skin is deepithelialized and the location for the dermal incision designed to leave behind a small dermal cuff is made. After release of the dermis, the defect can be seen to enlarge slightly.

Eight matching and evenly spaced points are marked on the areolar and periareolar incision lines. The PTFE suture is woven into the defect connecting the outer dermal cuff with small bites of the areolar dermis at eight evenly spaced points. The PTFE interlocking purse-string suture is cinched down to the desired diameter. Final closure is performed with a subcuticular absorbable monofilament.

In this technique, the same PTFE suture used in a standard purse-string technique is chosen; however, at eight evenly spaced locations around the periareolar defect, a small bite of the areolar dermis is incorporated into the placement of the suture. When the purse-string is cinched down, the areolar dermis is “locked” into the periareolar closure in a way that further stabilizes the dimensions of the defect and therefore the dimensions and shape of the areola. This technique has proved a very useful adjunct to periareolar surgery and provides secure, consistent control over the size and shape of the areola.

Markings

In preparation for periareolar mastopexy, the patient is marked in the upright position. The most important decision to be made is where to position the top of the areola. Quite simply, this becomes an artistic determination. By grasping the areola with the index finger and the thumb at the point at which the superior areolar incision will be made, the areola can be lifted in relation to the remainder of the breast. The areola is lifted just to the point where it is positioned at the point of maximum projection in relation to the breast mound, and this point is marked. The areola is then allowed to fall and the magnitude of the areolar lift can then be seen. By gently curving an oval around the medial, inferior, and lateral extent of the existing areola, the

dimensions of the periareolar pattern can then be determined. The marks are applied on each breast with care to ensure that the top of each pattern is symmetrically located from side to side.

To determine the top of the periareolar pattern, the superior aspect of the proposed periareolar incision is grasped and manually lifted up to the desired location. After marking the top of the periareolar pattern, the remainder of the incision is curved around the medial, inferior, and lateral extent of the existing areola to set the final pattern. It typically assumes the shape of an elongated oval.

Surgery

At surgery, the proposed areas of deepithelialization are infiltrated with a dilute solution of lidocaine with epinephrine to provide a vasoconstrictive effect and minimize bleeding. The areola is maximally and evenly stretched out to allow a 40 to 44 mm areolar diameter to be marked with the aid of a multidiameter areolar marker. The inferior half of the proposed areolar defect is incised and a small strip of dermis along the inner aspect of the incision is deepithelialized. The exposed dermis along the inside rim of the periareolar incision is then divided with Bovie cautery in such a way as to create a 5 mm dermal shelf. This shelf will serve as a very strong architectural framework to support the eventual purse-string suture. Access to the breast is obtained either by dissecting directly through the breast or by following the breast fascia inferiorly and curving down and around the breast to the level of the inframammary fold. There is theoretical advantage to using the inferior approach, since dissecting directly through the breast may expose the prosthesis to bacterial contamination from divided breast ducts, which potentially predisposes the breast to capsular contracture formation. Once the underside of the breast had been reached, any desired breast pocket can be developed. Care must be taken to ensure that the inframammary fold is properly positioned and the pocket is developed to the desired limits.

At this point, either the final implant or a sizer is inserted into the breast pocket and the proposed periareolar closure is temporarily stapled into position. With the patient placed in the upright position, adjustments in the elevation of the nipple-

areola complex can be made as needed to create the desired result. Once the final pattern is determined, the remainder of the periareolar defect is deepithelialized and the dermal shelf is created around the entire defect. An interlocking PTFE suture is placed and the areola is inset, with final closure with a subcuticular 4-0 absorbable monofilament suture.

Thus the volume of the augmented breast is set first, then the degree of final lift is determined. By sequencing the procedure in this fashion, the ability to adjust not only the volume of the implant, but also the final position of the nipple-areola complex is maximized, and miscalculations in either variable can be minimized. This approach is particularly useful in cases of preoperative asymmetry of the nipple-areola complex. By adjusting the position of each nipple-areola with the pocket dissected and the implant in place, the final position of the nipple-areola complex can be set in a controlled, predictable fashion.

This 35-year-old woman requested a periareolar augmentation mastopexy. Her preoperative markings show that the top of the areola will be lifted 3 cm to a point estimated to be 6 cm above the inframammary fold. This marking pattern is common for patients who present for augmentation mastopexy. The existing nipple position is 1 to 2 cm above the inframammary fold line. I placed 350 cc high profile smooth round silicone gel implants in the subglandular plane. Her 1-year postoperative result is shown.

Circumvertical Approach

When a periareolar approach will not be sufficient to provide the desired result, a circumvertical pattern is required. In these cases, a tailor-tacked vertically oriented inferior pole skin takeout is added to the periareolar pattern. This technique allows lifting of the nipple-areola complex, narrowing of the breast base diameter, and restoration of breast projection. Compared with the periareolar technique alone, the circumvertical pattern is a very effective method that can be used to not only lift the nipple-areola complex but also to reduce an excessive and ptotic skin envelope. This technique is so powerful that the need to resort to the use of an inverted-T pattern to manage the skin envelope is greatly reduced.

At times it can be difficult to predict preoperatively when a periareolar pattern will be sufficient to provide the desired result as opposed to when the addition of a vertical segment will be required. Simply put, whenever a vertical inferior pole skin tightening results in improvement of the breast contour, it is wise to add it. This school of thought values shape over scar and it must be recognized that the vertical scar more often than not heals in an imperceptible fashion when evaluated over time. In most instances, the improvement in the shape of the breast and the reduction in stress that is placed on the periareolar closure more than make up for the disadvantage of having to add the vertical scar. Familiarity with the CV pattern is one of the most powerful skills an aesthetic and reconstructive breast surgeon can acquire.

This 36-year-old woman presented for periareolar augmentation mastopexy with a smooth round silicone gel implant. The preoperative marks are shown; note that both nipples lie below the level of the inframammary fold.

The 1-year postoperative result shows mild widening of each areola, along with a mild capsular contracture on the right.

A right capsulectomy and a bilateral periareolar revision were performed. The 9-month postoperative result shows persistent mild periareolar distortion.

A bilateral periareolar scar revision was planned using the interlocking PTFE suture technique.

The areola was incised at 40 mm and the dermal shelf created. The interlocking suture was marked, and the PTFE suture was attached to a Keith needle. The interlocking suture is shown in place, cinched down to the desired diameter. The final closure is shown.

The final result at 7 months is shown, with correction of the periareolar distortion.

The patient's original lateral pre-operative appearance and her final 7-month postoperative appearance are shown.

Markings

As with the periareolar pattern, the patient is marked in the upright position. The top of the periareolar pattern is determined as before, and implant size and location is estimated based on the patient's wishes. The vertical segment is added by simultaneously lifting the position of the nipple-areola complex to the desired location, then pinching the skin of the lower pole together in a vertical line extending directly down from the bottom of the areola to the inframammary fold until a pleasing shape is created.

This 47-year-old woman presented for bilateral augmentation mastopexy; the circumvertical technique was planned. Circumvertical marks are shown. Note that the top of the periareolar pattern is positioned 6 cm above the inframammary fold line.

By drawing in the medial and lateral extent of this proposed skin excision, the general position of the vertical segment is estimated. The final vertical pattern will be determined intraoperatively once the implant is in place. However, identifying the general location of the vertical segment in this fashion allows an access incision to the breast to be drawn that will ultimately fall within the segment of skin that will be removed. Using this strategy allows free access to the breast for developing the pocket and positioning the implant without any concern about creating an addi-

tional cutaneous scar. With this in mind, a line is drawn within the center of the proposed skin excision, and it is this incision that will serve as the access portal to the breast to develop the pocket and place the implant. For more excessive skin envelopes, the inferior aspect of the vertical excision will curve out laterally along the inframammary fold rather than extend down below the fold. In these patients, the pattern assumes more of a canted V or a tornado-funnel shape, as opposed to a symmetrical V extending straight down the meridian of the breast. By curving the incision out laterally, more skin can be removed for a better breast shape without any of the wound-healing difficulties associated with traditional vertical skin patterns.

Surgery

As with the periareolar approach, all of the areas that will either be incised or deepithelialized are infiltrated with a dilute solution of lidocaine with epinephrine. The procedure is begun by first incising through the previously marked vertical skin incision. The desired pocket is created with care to preserve the location of the inframammary fold. The implant can then be inserted or, perhaps more preferably, a sizer can be used to add the desired volume to the breast. With the sizer or implant in place, the skin pattern as it was drawn preoperatively is tailor-tacked into place with staples and the patient is placed in the upright position, preferably all the way up to 90 degrees, if possible. This maneuver provides a very accurate assessment of the shape of the breast and the position of the nipple-areola complex. At this point, any alteration that is required to optimize the result can be made. Changes in the volume or projection of the implant, further defining of the pocket, or alteration of the position of the nipple-areola complex can all be made to provide the most shapely and aesthetic result possible.

As with a periareolar augmentation mastopexy, the operative strategy is to finalize the volume addition first and then tailor the skin envelope to fit this new breast size. Sequencing the procedure in this fashion provides a controlled and highly reproducible procedure that will minimize the likelihood of complications. Once these decisions have been finalized, the borders of the proposed skin takeout are marked with a surgical marker and the staples are removed after returning the patient to the supine position. The borders of the skin pattern, including the periareolar as well as the vertical components, are incised and the redundant skin deepithelialized. The same 5 mm dermal shelf used in periareolar procedures is created and the final implant is inserted. The vertical incision is closed in layers using an absorbable 4-0 monofilament suture. The patient is then returned to the upright position and the shape of the resulting periareolar defect is assessed. If it is not circular at this point, the opening is redrawn to approximate a perfect circle, and additional skin is deepithelialized as needed. Finally, an interlocking PTFE suture is placed to control the periareolar defect, and the areola is inset with a running subcuticular 4-0 absorbable monofilament suture to complete the closure. The wounds are dressed with tissue adhesive (Dermabond) and covered with an occlusive dressing (Opsite).

Once the pocket has been developed and the sizer or implant has been placed, the skin pattern is tailor-tacked into position to assess the shape and size of the breast (*left*).

After assessing the desired result, the edges of the plicated skin envelope are marked with a surgical marker and the staples removed (*right*). Here, the pattern can be seen to curve laterally along the inframammary fold just slightly because of the excess of the skin envelope. At the base of the pattern, the access incision used to create the pocket can be seen. Note that this incision falls within the confines of the vertical pattern that will be removed.

The redundant skin is deepithelialized and the final implant inserted into the pocket. The access incision is securely closed to prevent implant herniation as well as inadvertent lowering of the inframammary fold.

The areolar and periareolar margins are marked in preparation for placement of the interlocking PTFE suture. The PTFE suture is woven into the defect in an interlocking fashion, aligning the eight fixation points as accurately as possible. The final closure is completed.

The appearance of the right breast is shown after a 200 cc round smooth silicone gel implant was placed in the partial subpectoral pocket in conjunction with a circumvertical skin tightening. The difference in the appearance of each breast is readily apparent. The immediate appearance after operative correction of both breasts is also shown.

The early postoperative appearance reveals an aesthetic breast shape with good symmetry; the nipple is positioned at the apex of the breast mound created by proper positioning of the implant beneath the breast.

A bilateral circumvertical augmentation mastopexy was planned for this 44-year-old woman. Preoperative marks are shown; note that the top of the periareolar pattern is marked 6 cm above the inframammary fold line.

Her results are shown 1 year postoperatively.

Postoperative Care

The patient dons a support brassiere after surgery and is advised to wear the garment for at least the first week. When anatomically shaped implants are used, the support garment takes on greater importance, because the external support can help to hold the asymmetrical implant in the proper position while the pocket matures. In these cases, the patient is advised to wear the garment continuously for 6 weeks. No special straps, bands, or other external breast-shaping devices are required, since proper execution of a sound surgical plan will provide the desired result. Patients are seen 1 week postoperatively, when sutures are removed, and then at 6 weeks, 6 months, and 1 year. Typically the result will have matured by 6 months; however, full scar maturation can take a year or longer.

Complications

Using the described approach will afford the operating surgeon the maximal control over the final result and complications should be few. However, it is the nature of the procedure that complications may develop. As noted previously, it is useful to view augmentation mastopexy as more of a reconstructive procedure rather than a strictly controlled and focused aesthetic procedure such as primary breast augmentation. As a result of the increased number of variables that are being manipulated, the complexity of the procedure is greater and it is unavoidable that complications will develop. By doing the two components of the procedure together, however, the majority of the work is accomplished at the first procedure. Therefore, when problems do develop postoperatively, they are typically of less magnitude and are easier to treat than when the operation is staged. Although common complications inherent in any breast procedure such as infection, hematoma, delayed healing, capsular contracture and unattractive scarring may develop, there are several complications that are unique to augmentation mastopexy that merit specific mention.

Loss of Shape

Patients with breast ptosis severe enough to require mastopexy are a self-selected group of patients who are prone to postoperative settling of the skin envelope. In particular, patients who have undergone a large (more than 50-pound) weight loss are particularly prone to this problem. As well, simple aging or postoperative changes in weight, either up or down, can affect how the skin envelope complements the underlying volume of the implant. In each instance, ptosis of the breast parenchyma, the skin envelope, or the nipple-areola complex can become progressively worse over

time to the point where the shape of the breast is adversely affected. Typically, the implant will appear superiorly malpositioned on the chest wall with the soft tissue of the breast variably falling off the bottom of the inferior pole. It should be noted that these changes can occur whether the procedure is performed as a combined procedure or is done using a staged approach. Whatever the circumstance, typically all that is required to correct the deformity is to reapply the skin pattern using a tailor tack approach. Often the procedure can be performed using only local anesthesia. By retightening the skin envelope, the harmony of the breast with the breast implant can be restored creating a pleasing breast shape. It should be noted that mild capsular contracture can often contribute to an altered breast shape postoperatively. In these cases, it is important to treat the capsular contracture first and then retailor the skin envelope to provide the optimal result. Typically the amount of skin retailoring required to reshape the breast is minimal and easily done compared to the initial procedure and retightening the skin envelope is a straightforward operation. It is the unusual patient who requires a third skin tightening although such a procedure would be easily performed. The advantage of using the circumvertical pattern for these patients is that the pattern used to retighten the skin envelope is the same as was used initially, therefore no new scar is created. Such patients serve as an example of how powerful the C-V pattern is when used as a breast-shaping technique.

This 34-year-old woman is shown several years after undergoing a periareolar augmentation mastopexy. The position of her nipple-areola complex is low, and much of the breast has descended inferiorly off the lower pole of the implant. Preoperative marks show the plan for circumvertical tightening of the skin envelope without manipulating the implant. The 1-year postoperative result demonstrates an aesthetic improvement in the appearance of the breast.

Over several years, the patient had a mild weight gain and seemed to develop a disproportionate increase in the size of her breasts. Although the shape of her breasts was acceptable and the position of the nipple-areola complex was correct, she wanted a smaller breast size.

Preoperative marks are shown in preparation for an implant exchange; a mild circumvertical skin tightening was planned in anticipation of the creation of a mildly redundant skin envelope as a result of placing a smaller implant.

The 1-year postoperative result shows mild areolar asymmetry. A repeat circumvertical skin tightening was planned using the interlocking PTFE technique.

The 1-year postoperative result is shown. This case demonstrates the utility of the circumvertical pattern in managing several different postoperative concerns without the need to create additional scarring, yet it provides exacting control over the final result.

Asymmetry

For the same reasons noted for the loss of breast shape, it should not be a surprise that a small asymmetry in the shape or size of the breast or nipple-areola complex can develop postoperatively. Fortunately, correction of these asymmetries is just as straightforward. Because most of the work was done at the first procedure, the general relationship between the skin envelope and the implant can be seen directly once the result has stabilized. It then becomes a straightforward procedure to exchange an implant as needed, to lift or tighten the skin envelope, or reposition the nipple-areola complex using the interlocking PTFE technique. Such procedures are easily performed individually or together, and restoration of an aesthetic, symmetrical breast shape is usually easily performed.

Areolar Distortion or Widening

Problems with the size, shape, or position of the nipple-areola complex are complications specific to augmentation mastopexy. Fortunately, the interlocking technique has a particular advantage in these cases. Because scar has formed around the periareolar closure, the elasticity of the surrounding tissues is typically reduced. As a result, redoing the periareolar closure with or without a reduction in the size of the areola is facilitated, since the scar tends to hold the PTFE suture with a greater security than the dermal shelf created at the initial procedure. Also, the magnitude of the change in the diameter of the areola is usually less significant in a revision procedure; therefore less stress is placed on the periareolar closure.

One caveat to redoing an areolar closure relates to the shape of the breast. If the projection of the breast is flattened as a result of the periareolar incision or the dimensions of the periareolar defect are greater than 8 to 10 cm, it may be wise to add a vertical component to the skin pattern. This maneuver will tend to counteract the propensity of the breast to flatten and will help restore projection. The dimensions of the periareolar defect will become less significant, and stress on the periareolar closure will be reduced. As with other skin envelope complications, such revisions are easily performed and can often be done with a local anesthetic with a high degree of control and predictability.

Results

This 43-year-old woman sought augmentation mastopexy. She had ptosis of the nipple-areola complex but did not want any type of vertical scar. The preoperative marks for periareolar augmentation mastopexy represent the limit to what can be done successfully using only a periareolar approach. The patient is shown 6 months after placement of 300 cc round smooth silicone gel implants in the subglandular plane. The size and shape of the breasts are acceptable, and the nipple-areola complex is at the point of maximal projection. However, the aesthetics of the periareolar scar have been compromised because of the magnitude of the periareolar lift. To avoid such areolar distortion would have required the use of a vertical segment in addition to the periareolar component.

This 41-year-old woman requested an augmentation mastopexy. Not only did her nipple-areola complex require lifting, but also the skin envelope needed to be reduced. Therefore a circumvertical pattern was planned to manage the skin envelope. The preoperative marks show the degree of lift for the nipple-areola complex. On the right, a 275 cc smooth round silicone gel implant was placed subglandularly, and a 250 cc implant was placed on the left. She is shown 2 years postoperatively; a full, rounded breast has been created, with the nipple located at the apex of the breast mound.

Concluding Thoughts

Augmentation mastopexy is one of the most challenging of all aesthetic breast procedures. However, with careful planning and judicious management of the redundant skin envelope, excellent results can be obtained in one operation.

Clinical Caveats

Periareolar mastopexy should be limited to patients who predominantly need lifting of the nipple position, preferably a lift of 3 cm or less.

The circumvertical approach is appropriate for patients who require reduction of an excess skin envelope in addition to lifting of the nipple.

The interlocking suture technique provides extra control over the position, size, and shape of the areola.

Tailor-tacking can be used to predetermine final breast shape before actual incisions are made.

Ideally the augmentation is performed first, then the mastopexy, to be certain that the two maneuvers optimally complement each other.

Overaugmentation in an augmentation mastopexy patient may lead to dissatisfaction because the breasts are too large.

CHAPTER 67

Control and Precision in Mastopexy

JAMES C. GROTTING, STEPHEN M. CHEN

Perhaps no other aesthetic procedure is characterized by as much anticipation by the patient—and long-term potential for dissatisfaction—as mastopexy, the procedure for treating ptosis. The problem with this aesthetic breast deformity is that all the forces that lead to its occurrence continue postoperatively to strongly influence the end result. This is the reason that mastopexy has traditionally been viewed as a semipermanent procedure.

The goal of mastopexy is well understood by both patients and surgeons—that is, to construct a breast that is beautifully shaped, has long-term stability, and is appropriately sized. Nipple positioning must be precise, with preserved sensibility, shape, and size. Preservation of lactation and minimal visible scarring are essential.

Sometimes patients have a breast shape in mind that they had earlier in life or before pregnancy or weight loss. Other patients, as a result of genetics or constriction, may have developed a “droopy” breast shape, even in adolescence, that has long been a source of dissatisfaction or embarrassment. Patient education is essential; many women enter the plastic surgeon’s office with the misconception that ptosis can be corrected simply by the addition of a breast implant.

It is interesting that most patients indicate the shape they desire by lifting (pulling) the gland above the nipple-areola complex to lift and tighten the lower pole. However, most of the procedures that we have to offer to treat ptosis consist of tightening the lower pole to push the gland up from below. In this chapter we will focus on procedures that have produced the most reliable results and on recent trends toward reduction of scar length.

Common Causes of Breast Shape Deformities

Clearly, understanding the forces that have produced a certain breast shape is important so that one can design a strategy to correct it. Most women who have had one or more pregnancies experience an adverse effect on breast shape. The processes of lactation and hormonal influences produce breast enlargement that stretches skin, supporting ligaments, and even the ductal and glandular structure itself. Once these changes overtax the ability of the elastic tissues to recover, the result is a loss of the ability of the breast to maintain its position on the chest wall. The smaller the breast to begin with, the more likely it is that the breast will not become overly ptotic; women with large breasts invariably become more ptotic after pregnancy. Ptosis resulting from weight gain and subsequent weight loss produces similar damage to breast shape. This etiologic factor is fast becoming one of the most common reasons patients seek mastopexy as weight-loss surgery becomes more and more prevalent.

Changes in the breast caused by aging can also produce symptoms similar to macromastia. As women try to counteract drooping breasts by tightening their bra straps, more pressure is placed across the shoulders, resulting in neck and shoulder pain. Furthermore, the moisture in the inframammary fold area caused by skin-on-skin contact can produce intertrigo or fungal dermatitis.

One other common category of breast ptosis is seen long term after a breast augmentation procedure. Not uncommonly, these patients were originally treated (and, it could be argued, inappropriately) with breast implants to correct minor ptosis. Often the surgeon may place a larger implant in the subglandular position to attempt to improve the droop. The long-term price paid for this approach is greater stress on all elements of the breast architecture and “rock-in-a-sock” deformities of the breast.

Common Causes of Breast-Shape Deformities

- Changes after pregnancy
- Weight gain and subsequent loss
- Aging
- Long-term changes after breast augmentation
- Developmental deformities during adolescence

Classification of Breast Ptosis

Regnault's classification of breast ptosis remains a helpful way to communicate or record the severity of a deformity. By this classification, minimal or first-degree breast ptosis is present when the nipple position is within 1 cm of the anterior reflection of the inframammary fold and above the lower contour of the gland, whereas moderate or second-degree breast ptosis is defined as a nipple position 1 to 3 cm below the fold but still above the lower contour of the gland. In severe or third-degree breast ptosis, the nipple position is more than 3 cm below the fold and below the lower contour of the skin and gland.

Pseudoptosis is another variant of breast shape in which the nipple is actually at or above the level of the fold but the majority of the gland is below, producing the impression that ptosis is present. It is important to recognize this deformity so that the corrective plan does not result in positioning the nipple too high.

Patient Evaluation

In one sense, many of the patients who complain of breast ptosis can be viewed as having “too much skin” for the amount of breast tissue they have. However, equally important is the quality of the skin and breast parenchyma in designing an appropriate procedure for them. Some patients with breast ptosis also have an element of macromastia, which exacerbates the shape problem. Although the goals of some patients may be to retain a large size with a perfect shape, these two elements often be-

come mutually exclusive with time. In other words, the effect of gravity alone on a large mass of breast tissue will invariably result in recurrence of ptosis. Therefore a reduction of some breast parenchyma may be an important component of the treatment plan. Conversely, adding mass with a breast implant can potentially expedite the recurrence of ptosis by the same mechanism.

Preoperative Physical Characteristics to Observe During Initial Evaluation

Skin quality: Thickness, color, striae, and amount of excess skin

Fat: Quality and content

Fibrous tissue: Quality and content

Nipple: Size and shape

Areola: Size, shape, and color

The primary question that must be addressed is whether the patient would benefit from the use of an implant. A good question to ask the patient is, “Can you make your breasts look the way you want them to look in a bra?” If the answer is “Yes,” then the patient can usually be treated with a mastopexy alone. If she is doing something to enhance volume (for example, wearing a padded bra or using an insert), she may also benefit from an implant. Of course, the problem with a combination of mastopexy and implants is that, in a sense, the two operations are working against each other. The natural tendency after an augmentation is for the tissues to eventually move down and out—exactly the opposite of what the mastopexy is designed to do. Therefore we prefer to delay implant placement in patients who are ambivalent about being larger. Persoff has chosen to solve this dilemma by using a postoperatively adjustable Spectrum (Mentor) implant. Obviously, there are patients in whom good shape or adequate size cannot be achieved without the addition of an implant, and in these individuals the plan must include an implant. Further, practical considerations such as cost and time away from work or family may dictate that an augmentation and mastopexy be combined in one procedure.

Once the decision has been made regarding placement of an implant, the evaluation continues with a few helpful measurements. Specifically, the distance from sternal notch to nipple on each side identifies asymmetry. Photographs are also indispensable for this judgment. The distance between the nipple and the inframammary fold will also help determine whether a periareolar, vertical, or inverted-T approach is necessary. As the distance shortens, it is more likely that only a periareolar approach will be required. If the areola is large and the distance short, the situation is ideal for

the periareolar approach. Conversely, as striae increase in number, it is more likely that additional skin will need to be excised because of the unpredictability of skin retraction in these patients. The need for additional volume must be balanced by the quality of support from the parenchyma and skin. If the quality is poor to begin with, it is foolish to assume that the long-term result will remain good, and the surgeon must augment the supporting structures.

With the patient standing, the surgeon gathers the lower pole with the hand to simulate the upper pole fullness and medial cleavage desired. This movement allows the surgeon to see the patient's reaction to the new shape. Some patients will view this and agree that that appearance is what they want; others will offer additional information that will help define their goals. The surgeon can make a mental note of how far the nipple must be elevated. If minor elevations are necessary, one might consider a periareolar technique (or even a semicircular skin excision). Only the most severe cases require an inferior pedicle or a medial or lateral pedicle so that the nipple-areola complex can be rotated without tension. The pedicle will also influence the position of the implant above or below the muscle. For example, an inferior pedicle would preclude use of a subglandular implant in most cases.

Operative Technique

Selection of Technique

Mastopexy techniques generally fall into the simple skin-tightening-only procedures, or the parenchymal remodeling methods. Because skin is elastic, skin-only techniques tend to produce a shorter-lasting correction and are appropriate if less elevation is required or if one does not wish to violate the parenchyma at all (for example, op-

posite breast corrections with breast reconstruction). This can be likened to procedures of the face, where we now recognize that tightening only the skin will not yield a natural, long-lasting result. With patients who have both hypomastia and ptosis, the surgeon must decide whether to try to correct ptosis with an implant alone. In general, correcting ptosis with large subglandular implants ultimately leads to a lower breast position, a short distance from the lowered inframammary fold to the iliac crest, and difficulty in fitting clothing. Although patients may initially accept the appearance, in time many return to the plastic surgeon's office seeking correction. Improved nipple position on a lowered glandular profile is not an adequate tradeoff for the original problem of shape and size. Correction, of course, requires some type of mastopexy and usually smaller implants.

The differences between skin-only mastopexy techniques and parenchymal remodeling techniques can be summarized as follows:

Skin-only techniques: Less permanent

Parenchymal remodeling: Longer-lasting correction of ptosis techniques

The issue of implant size must be considered if implants are to be used. Mastopexy patients already have stretched-out skin, and large devices very likely cannot be supported long term by the tissues, so it is generally safer and more predictable to place a smaller base-width implant with less volume. Because patients often confuse size with shape, a reasonable strategy for the patient with larger volumes of native tissue is for her to live with the lift alone for the first year and consider tweaking the result with an implant if she really desires more size at the 1-year mark. Many of these patients will realize that the shape is what they desire more than just increased cup size. When the breast parenchyma is very thin, soft, and fatty, it generally will not hold shape well, and therefore we prefer skin-only tightening in this group of patients and virtually always include an implant.

Skin Incision and Ultimate Scar Shape Versus Dermoglandular Pedicle

Many surgeons confuse skin incision and pedicle location as being interchangeable when in fact they are two independent variables. Skin incisions are based on the amount of excess skin that needs to be removed to produce a more pleasing breast shape, whether it be smaller and rounder or larger and rounder. Pedicles about the breast are numerous, whether they are located superiorly, inferiorly, superomedially, laterally, are bipedicled, and so on. The important concept is that the nipple must be given a base to survive and the underlying gland must be shaped so that it will aid in a long-lasting correction of a deflated breast.

Periareolar Techniques

No mastopexy technique is as seductive as the periareolar technique. By this we mean that as tempting as it is to confine incisions to the areola-skin interface, the method can lead to poor results if applied to the wrong patient. Clearly, all patients and surgeons would prefer to keep scars concealed and as short as possible, as long as a beautiful shape can be produced. When the proper technique is executed in a properly selected patient, the periareolar technique confines incisions and therefore potential scars to the areola-skin interface. Resulting scars in this area are usually almost unnoticeable if the surgeon diligently makes the incision precisely where the areola and breast skin meet. If the incision extends either onto the areola or the skin, more noticeable and less satisfactory scars can result, and the primary benefit of this technique is lost. Subsequent correction of these poorly positioned scars may lead to further spreading of the areola and poor aesthetic results.

The periareolar approach is most appropriate in cases of mild to moderate breast ptosis where there is adequate, firm glandular parenchyma. If a patient has mild to moderate breast ptosis but a small or atrophic gland, a small implant may be added in certain periareolar techniques to achieve a pleasing breast shape.

The simplest periareolar technique involves excising or deepithelializing skin around the areola. Depending on the degree of ptosis and the location of the nipple, the skin excisions can be designed in a doughnut or crescent shape.

Small, mildly ptotic breasts with adequate breast parenchyma respond best to this technique. However, this technique can be modified to accommodate moderate degrees of ptosis and for patients who lack adequate breast parenchyma. The usual modification in such a case is the addition of a small implant to take the place of breast tissue and to fill the skin envelope. Usually nipple position remains low after this augmentation, and simultaneous removal of skin around the areola allows elevation of the nipple-areola complex to a more anatomically desirable position. It is difficult to achieve more than 2 to 3 cm of nipple elevation using these simple skin-only designs.

As with all periareolar techniques, the main advantage is a minimal incision with placement where the resulting scar can best be camouflaged. Even if an implant is needed, this can be placed through the same periareolar incision used to excise the excess skin.

The primary disadvantages have to do with the requirement for meticulous precision in the placement of the incision and the amount of skin excised. Even with precision, the resulting scar can widen because of excessive tension on the closure,

either as a result of overaggressive skin excision or trying to use this procedure to treat significant breast ptosis. If a patient requires more than 3 cm of nipple elevation, we usually opt for a vertical incision. Sometimes the weight of the implant can put too much tension on the closure. In addition, the patient's skin quality (thickness and elasticity) can be a major factor in the quality of the final scar. It is not a coincidence that women with poor skin quality are most likely to present with complaints of ptosis.

Excessive tension on the closure may also cause the breast to assume a flattened shape with poor projection. This must be avoided, because a good scar loses its value if placed on a misshapen breast.

Periareolar Mastopexy Without Parenchymal Reshaping

Technique

The position of the nipple-areola complex determines the amount of skin to be excised. It is critical to resect only the amount of skin necessary to raise the nipple to correct the ptosis. Additional consideration must be made for any excess areola that is to be removed.

The lines of excision are marked on the breast with the patient in a sitting or standing position in the preoperative area. Symmetry is ascertained using the sternal notch-to-nipple distance and the sternum-to-nipple distance. In the operating room, the amount of the areola that is to remain is marked under tension using an areolar marker. According to Spear et al, the amount of nonpigmented skin excised should be less than the amount of pigmented skin excised. The skin between these two marks is infiltrated with 0.5% lidocaine with 1:200,000 epinephrine to facilitate deepithelialization. Once the epidermis is removed, the edge of the dermis can be elevated. The skin around the outer edge of the exposed dermis is elevated off the gland for a short distance superiorly. The freed dermis can then be tacked to the gland under the elevated skin for additional support for the new nipple position. A purse-string suture of 4-0 Gore-Tex or Mersilene is then placed in the deep dermis of the skin edge. This is then cinched to the approximate size of the areola and tied. The areola is tacked to the skin with half-buried horizontal mattress sutures, followed by a running Monocryl or PDS subcuticular stitch.

The Benelli Periareolar Mastopexy Technique

Dissatisfied with the limits of simple periareolar techniques, Benelli devised modifications of periareolar mastopexy so that the periareolar technique could be applied to larger breasts with increasing degrees of ptosis. In addition, Benelli's technique could be applied in cases of breast hypertrophy as well as tumor excision, with the main goal of limiting the scar.

Benelli's technique treats the skin and gland as two separate components. The periareolar approach affords access to the underlying gland, which is then separated from the overlying skin. A vertical dermatoglandular flap is created with lateral and medial extensions that are subsequently crisscrossed to make the glandular mound cone shaped. The tissue contiguous with the vertical flap inferiorly can either be excised or imbricated, depending on the volume needed for good breast shape. The end result is a narrower breast with a tightened inferior pole. The skin envelope is then redraped over this newly formed glandular scaffold. A "round block" cerclage stitch is used as in the doughnut mastopexy to help control tension at the areola-skin junction. As can be seen, this technique allows a more precise shaping of the breast with the inverted-T incision through the gland, while requiring no additional incisions to the skin.

This technique expands the range of periareolar mastopexy to incorporate greater degrees of ptosis as well as the ability to treat glandular excess. As with the skin-only techniques, an implant can be used to provide superior pole fill.

The Benelli technique is not beneficial for women who have severe degrees of ptosis and/or very poor skin quality. Potential pitfalls of this technique include its steep learning curve as well as the temptation to apply this technique when it is not indicated. The usual complications that arise when attempting this are a flattened appearance of the breast and a widened areola as a result of overresection of the skin and/or improper glandular support. The unwary surgeon may produce a very unsatisfactory outcome using this concept.

Technique

Preoperative markings are performed with the patient upright by first marking the midline and estimated meridian of the newly shaped breast (usually located 6 cm from the midline in a position medial to the original breast meridian). Point A, the future superior border of the areola, is marked 2 cm above the anterior projection

of the inframammary fold in line with the new breast meridian. Point *B*, the future inferior border, is marked with the patient recumbent and is located 5 to 12 cm above the inframammary fold after taking the final estimated volume and the amount of skin resection into consideration. Points *C* and *D* (the medial and lateral limits of the new nipple) are equidistant from the meridian. Point *C* averages 8 to 12 cm from the midline. Like point *B*, these marks are based on the anticipated final volume. Point *S* is the point at which the breast meridian intersects the inframammary fold.

The opposite breast is marked in a similar manner, depending on the degree of asymmetry inherently present. The resection margins are simulated by pinching together points *A* and *B* and then *C* and *D* to verify adequate skin coverage without tension. A wetting solution consisting of saline solution (1000 ml), epinephrine (0.25 mg), and 2% lidocaine (20 ml) is infiltrated subcutaneously in the area that will be detached. The ellipse and surrounding 3 cm are not infiltrated to preserve the vascularity of the skin edges. The prepectoral area is also infiltrated.

The desired areolar diameter is marked and the periareolar ellipse deepithelialized. The deepithelialized dermis is incised from the 2 o'clock to the 10 o'clock positions. The dissection is extended toward the inframammary fold in the subcutaneous plane.

The dissection continues to the upper-outer quadrant of the breast, with the dissection becoming more superficial to preserve the vessels coming from the lateral thoracic artery. Next glandular dissection is initiated with a semicircular incision approximately 3 cm from the inferior areolar edge to preserve innervation and the blood supply to the areola. Dissection is continued to the prepectoral space in the avascular central space, preserving the peripheral blood supply.

The inferior glandular flap is then cut vertically beyond the breast meridian up to the fascia. Four flaps will thus have been elevated: (1) a superior dermoglandular flap supporting the areola, (2) a glandular medial flap, (3) a glandular lateral flap, and (4) a detached skin flap.

These glandular flaps will be reassembled and repositioned to decrease the base of the breast, thus promoting the lifted appearance. If necessary, these flaps can be trimmed to reduce unwanted fullness. Volume reduction at the distal ends of the flaps will limit their length.

On completion of the gland resection, the gland is lifted by stitching the superior flap high up on the pectoralis fascia to produce an exaggerated bulge in the superior pole of the breast. The nipple should be raised by this maneuver as well. Over the next few weeks, the superior roundness will flatten from the effects of gravity.

Next the medial and lateral flaps are folded over one another and sutured in place by rotating and folding the medial flap behind the areola, fixing its distal portion to the pectoralis muscle with superficial stitches. Then the lateral flap is crossed over and fixed to the medial flap. The movement of these flaps reduces the base of the breast, forming a glandular cone on which to place the areola.

If the gland requires no resection, a plication invagination can be performed to achieve conization and elevation of breast shape.

The areola is fixed to the superior border of the ellipse through a 1 cm dermal window made near the superior skin edge (the 12 o'clock position). This allows the knot to be buried and the areola to be supported without tension on the skin. Support for the breast shape is achieved by full-breast lacing. Braided polyester suture material on a long straight needle is used to create large inverted sutures along the underside of the gland. The superior stitch should pass through the superior dermoglandular flap, allowing control of the anterior projection of the nipple-areola complex. These full-breast lacing sutures should be applied without tension, their goal being to provide passive support of the newly created conical breast. Tying these lacing sutures too tight can result in glandular necrosis.

The skin is redraped over the breast. A round block cerclage stitch is passed in the deep dermis in purse-string fashion. It is then cinched around an areolar template of the desired diameter, ensuring even distribution of the skin pleats. The block stitch is then tied, burying the knot in the previously created dermal window. Further regulation of the projection of the areola is accomplished by an inverted dermoareolar stitch, which takes a large vertical bite in the areola and a large horizontal bite in the dermal ellipse. This helps to evenly distribute any remaining deep pleats around the areola.

A diametrical transareolar U suture (point) is placed to serve as a barrier and to help prevent areolar protrusion. It also can be used to give a circular shape to the areola in cases in which the areola tends to be ovoid. A 4-0 Vicryl intradermal suture around the areola completes the procedure.

The site is dressed with a wet compress on the areola and dry compresses on the detached skin, held in place by an adhesive bandage of moderate compression to prevent hematoma. These are removed on postoperative day 2, along with any drains, and are replaced with a sterile, ultrathin, semiocclusive polyurethane foam adhesive pad. This dressing covers the areola and scar and maintains all of the detached skin in place. This pad will be changed weekly. The patient wears a mammary support bra day and night for 2 months.

Góes Periareolar Technique With Mesh Support

João Carlos Sampaio Góes of Brazil expanded the use of periareolar techniques by introducing his *double-skin technique* whereby a resistant lining of the breast is created with the use of a layer of prosthetic mesh. The “double skin” refers to the use of a doughnut-shaped, periareolar, deepithelialized dermal flap that is used to support the gland under the remaining normal skin, which will be closed around the reshaped gland. The mesh provides increased support of the new breast shape during the healing and skin contraction processes rather than depending on stretched-out breast parenchyma and skin.

Sampaio Góes treats the glandular unit separate from the overlying skin. He creates an internal brassiere by using the anterior pectoral fascia, inframammary connective ligaments, a periareolar dermal flap that is used as an internal lining, and a mixed mesh originally composed of Vicryl and Prolene (Ultrapro by Ethicon). This is enveloped by the external skin.

This method is very useful for correcting ptosis or for small reductions of mammary hypertrophy with or without ptosis. The reduction volume should ideally be less than 500 g. As with all breast surgery, better aesthetic results are obtained in younger patients who have firm tissues, more elastic skin, and little fatty tissue.

In addition to limiting the scar to the periareolar region, the main advantage of this technique is the use of the mixed mesh to create a long-lasting correction for the ptotic breast. The mechanism is an intense fibrosis around the mesh, which causes scarring. This results in an initially rigid breast for the first few months, which then softens as the scar matures. However, despite the fact that internal scarring occurs, the mesh that remains is integral to maintaining the correction. Ultimately, the breast feels normal on palpation—the mesh is not palpable, and it does not interfere with mammographic evaluation.

The drawbacks of this technique lie in the steep learning curve associated with this technically difficult operation. In addition, there are the theoretical problems of mesh extrusion, infection, or skin necrosis. It is imperative to carefully dissect the skin flaps and to place the mesh meticulously to avoid suboptimal results and/or disastrous outcomes.

There has also been considerable resistance to placing permanent foreign bodies within the breast parenchyma among U.S. surgeons because of concerns about mammographic artifacts or palpability; de Bruijn and colleagues in Belgium have addressed this with the use of a three-dimensional polyester mesh that does not cause artifacts on mammography and is not palpable. Histologically, there is minimal scarring and a deposition of a thin layer of collagen about the mesh that results in increased firmness of the breast parenchyma to provide a long-lasting correction.

Technique

The technique begins with the preoperative marking. The most important concept is to leave adequate skin to cover the new breast mound. With that in mind, four cardinal points are marked. Point A is the level of the top of the new areola; point B is the distance from the inframammary fold (on average, 7 cm); point C is the distance from the midline to the medial margin at the level of the nipple (usually 9 cm); and point D is the distance from the anterior axillary line to the lateral margin at the level of the nipple (usually 12 cm).

The marked area is deepithelialized to the nipple. The outer border is incised and a skin flap is developed superiorly, with progressive thickening of this flap as one approaches the chest wall. The undermining continues for another 5 cm once the pectoralis fascia is reached. The direction is then changed inferiorly under the gland to approximately a third of the retromammary space. Perforators will be encountered and should be preserved. Inferiorly, a thin flap is developed down to the inframammary fold.

After the skin and breast parenchyma are separated into components, any excess tissue can be resected in a wedge shape at the superior and inferior poles of the breast mound. None of the tissue at the base of the mound should be excised. The gland is then shaped by suturing the gland together superiorly and affixing it to the chest wall to provide fill of the upper pole of the breast. Likewise, the inferior resection is sutured together and then fixed to the inframammary connective ligaments and the anterior pectoral fascia. The deepithelialized flap is stretched out over the new breast mound, attaching it superiorly to the connective ligaments of the breast and inferiorly to the anterior pectoral fascia. This creates the internal skin lining.

The next step places the mesh over the newly created mound and internal skin lining to function as a brassiere that will elevate the breast and provide a stable base for achieving a conical shape. The mesh is affixed to the anterior pectoral fascia at the base of the breast mound.

The external skin lining is brought up over the breast mound and closed around the areola with a circular, continuous, deep intradermal suture of Mersiline 2-0 on a straight needle. A continuous intradermal Monocryl 4-0 suture is used to fix the areola skin to the external skin lining. Dressing consists of triangular pieces of Micropore tape covering the whole gland, which is left in place for 20 days. Tegaderm also works well for this purpose. Suction drains are removed after approximately 5 days.

Excessive tension on the closure can also result in the breast assuming a flattened shape with poor projection. This must be guarded against, because a good scar loses its value if placed on a misshapen breast.

Vertical Mastopexy Without Implants

We believe that some type of parenchymal remodeling is essential to produce a longer-lasting lift effect in a mastopexy without implants. As mentioned previously, a vertical or inverted-T deepithelialization with skin tightening alone is appropriate only in certain patients. These are the women for whom the surgeon deliberately chooses not to violate the parenchyma for follow-up imaging considerations, such as opposite breast mastopexy for matching a reconstructed breast. Otherwise, it is my view that rearrangement of the parenchyma gives a more satisfactory long-term lift. The way that we most commonly way accomplish this is with a superiorly based flap from the midline of the lower pole turned underneath to provide fill to the upper pole. The medial and lateral pillars developed by the flap are approximated to tighten the lower pole and narrow the breast if it is too wide.

Marking

The breast is marked with the patient standing with her arms at her sides. We prefer to sit in front of her on a stool, which can be raised and lowered so that the surgeon always views the patient from the same perspective, regardless of how tall she is. By doing that, the surgeon can learn from past errors with nipple position and so forth, and the line of sight will be very similar on the next patient so markings can be adjusted.

The inframammary fold is marked on each side. The new nipple position is assessed. This is determined by a combination of data points. First the inframammary fold is transposed to the anterior surface of the breast and marked. Then the lower pole breast tissue is gathered to simulate the pexy to see if the nipple seems to elevate to the marked point. The point is checked against the midhumeral horizontal line and the distance between the sternal notch and the new nipple position is measured, usually 20 to 23 cm. Symmetry and distance from the sternal notch are checked. If any of

the parameters are vastly disparate, adjustments are made. Final nipple position is usually determined intraoperatively after the vertical closure, so the initial point merely represents a best guess. The next mark is the midline of the breast on its anterior surface. We aim toward the lateral border of the neck as if a tape measure were draped around the neck, as some surgeons have recommended. The midpoint of the inframammary fold is also an important landmark because this is where the bottom of the vertical limbs will be centered.

The breast is then gently distracted laterally so that the medial pillar can be marked in line with the midline superiorly and inferiorly. The mark is joined with the inferior mammary midline with a curvilinear line that ends a few centimeters above the inframammary fold. The same maneuver in the opposite direction defines the lateral pillar. It is most important to view the shape and volume of the tissues left behind (outside of the pillar markings), because these will determine the ultimate shape of the breast.

Once the vertical markings are positioned, these are drawn into a parabolic shape inferiorly, ending 2 to 3 cm above the native fold. Superiorly, the lines are curved up to the new nipple point, taking no additional skin around the nipple-areola complex initially.

The top of the vertical closure is estimated by the pinch technique so that not too much skin will be required to be gathered in the periareolar closure. The secret to good periareolar scars is to make certain this is closed without excessive tension. For smaller mastopexies, the periareolar circle is marked for deepithelialization if we are confident that the nipple position has been properly determined. The greater the degree of ptosis, the less likely we are to commit to the new nipple position definitively.

From the top of the vertical closure, one measures down 5 to 6 cm and makes another mark that will represent the approximate position of the new fold. The breast tissue below that point will comprise the bottom of the superiorly based flap or will be trimmed. Any convexities in the axillary area that may need suction contouring must be marked.
